Abstract

The study of soil N cycling processes has been, is, and will be at the center of attention in soil science research. The importance of N as a nutrient for all biota; the ever increasing rates of its anthropogenic input in terrestrial (agro)ecosystems; its resultant losses to the environment; and the complexity of the biological, physical, and chemical factors that regulate N cycling processes all contribute to the necessity of further understanding, measuring and altering and mitigation of the soil N cycle. Here, we review important insights with respect to the soil N cycle that have been made over the last decade, and present a personal view on the key challenges for future research. We identified four key questions challenges with respect to basic N cycling processes producing gaseous emissions:

1. How large is the contribution of non-symbiotic N fixation in natural systems?
2. How important is nitrifier denitrification and what are its main controlling factors?
3. What is the greenhouse gas mitigation potential and microbiological basis for N₂O consumption?
4. How can we characterize hot-spots and hot-moments of denitrification?

Furthermore, we identified a key challenge with respect to modelling:

1. Disentangling gross N transformation rates using advanced $^{15}\text{N}/^{18}\text{O}$ tracing models?

Finally, we propose three key questions challenges about ecological interactions controls on N cycling processes:

1. How does functional diversity of soil fauna affect N cycling processes beyond mineralization?
2. Determining What is the functional relationship between root traits and soil N cycling?
3. Characterizing the control—To what extent do different types of mycorrhizal symbioses (differentially) exert on N cycling?  

4. Quantifying the contribution of non-symbiotic pathways to total N fixation fluxes in natural systems;  

Finally, we identified a key challenge with respect to modelling:  

4. How can advanced $^{15}$N-$^{18}$O tracing models help us to better disentangle gross N transformation rates?  

We postulate that addressing these questions would constitute a comprehensive research agenda with respect to the N cycle for the next decade. Such an agenda would help us to meet future challenges on food and energy security, biodiversity conservation, water and air quality and climate stability.
1. Introduction

Humankind's relationship with soil nitrogen (N) has been a long and troubled one. For most of agricultural history, farmers have struggled to maintain soil fertility levels in their fields, relying mostly on biological N fixation (BNF), decomposition of soil organic matter and redistribution of organic materials to provide N to their crops. With the onset of large-scale application of mineral fertilizers after World War II in the 1950's, the main focus in large parts of the world has gradually shifted towards minimizing harmful losses to the environment resulting from the large amounts of N entering the global food production system (Galloway et al., 2013).

The history of research on the soil N cycle reflects this shift. The study of N cycling processes started after Carl Sprengel's discovery (popularized by Justus Von Liebig) of the importance of N as a factor limiting the growth of crop plants in the mid-19th century (Gorham, 1991). More than 150 years of research has demonstrated that this element limits ecosystem productivity over large areas of the globe and is highly sensitive to changes in temperature, precipitation, atmospheric CO₂ and disturbance regimes (Galloway et al., 2008). Since the 1960s, following the realization that excess N has negative effects on water, air and ecosystem and human health (Compton et al., 2011; Davidson et al., 2012), the study of the N cycle has intensified, focusing on N loss pathways next to the more traditional study topics such as plant N uptake. Most recently, the realization that the response of ecosystems to global environmental change would to a large extent depend on N dynamics (Van Groenigen et al., 2006; Luo et al., 2011) has generated further interest in the soil N cycle. Clearly, our ability to understand, manage and adapt to food security issues and global environmental change is limited by our knowledge of soil N-cycling processes: their nature, size, flux rates and dynamics in response to a myriad of environmental factors.
The increased need for information on soil N cycle processes rates has coincided with a revolution in the ability to characterize the microbial communities that carry out these processes using molecular techniques. This revolution has been both a help and a hindrance to the effort to quantify process rates. While efforts to extract DNA and RNA and to define microbial communities and diversity have produced fascinating new information on the agents that carry out apparently ever-more complex soil N cycling processes (Isobe and Ohte, 2014), we still lack basic information on the rates of several key processes, and the extent to which they are controlled by biotic interactions in the rhizosphere.

The need for more information on soil N cycling process rates is highlighted by large amounts of “missing N” that dominate N balances at all scales. Inputs of N through fertilization, BNF, atmospheric deposition and human- and animal waste have been found to be substantially higher than hydrological outputs of N in many studies, at many scales (Howarth et al., 1996; Boyer et al., 2002; Groffman, 2008). There is much uncertainty about the fate of this excess N (Van Breemen et al., 2002). Is it stored in soils or vegetation? Is it converted to gas, and if so, in which forms? This uncertainty is particularly compelling in agricultural systems which receive high rates of N input causing great concern about the air and water quality impacts of these N exports in these systems are a cause for great concern (Davidson et al., 2012). In other ecosystems, on the other hand, there is concern about missing N inputs. Unexplained accumulation of N in aggrading forests (Bernal et al., 2012; Yanai et al., 2013) or in vegetation exposed to elevated levels of atmospheric CO₂ (Zak et al., 2003; Finzi et al., 2007) suggest unmeasured inputs of N via BNF (Cleveland et al., 2010) or uncharacterized
mechanisms of soil N turnover and mineralization (Drake et al., 2011; Phillips et al., 2011; Phillips et al., 2012).

Here, we review important insights with respect to the soil N cycle that have been made over the last decade, and present our view on the key challenges for future soil research. A particularly pressing need in N cycling research has been in the area of gaseous emissions, especially of those that contribute to global warming. As a part of the post Kyote international negotiation process on greenhouse gas mitigation action plans, gaseous N emissions from soils have received renewed attention (Groffman, 2012). The role of soil biogeochemists is to generate field data on terrestrial greenhouse emissions, but high uncertainties in soil N₂O and N₂ budgets still exist. Much of this uncertainty arises from in large part, the latter is attributed to a lack of information about the importance of the variety of the many gaseous N gas forming processes occurring in the soil and the methodological constraints that impose limits on to their flux measurements (Ambus et al., 2006). Evidence is emerging that processes, other than nitrification and denitrification, are far more important than previously assumed for gaseous N production from soils. Processes such as nitrifier denitrification (Wrage et al., 2001), in-situ N₂O reduction (Schlesinger, 2013), anammox (Mulder et al., 1995), ammox (Sawayama, 2006), dissimilatory nitrate reduction to ammonium (DNRA) (Tiedje, 1988), and codenitrification (Spott et al., 2011) have all been hypothesized to play a role in the gaseous N cycle. Novel and fascinating efforts to extract DNA and RNA and to define microbial communities have recently produced new information on the agents that carry out many of these processes (Isobe and Ohte, 2014). Yet, information on process rates and their
dynamics in response to a myriad of environmental factors are clearly lacking behind. Such information is, however, vital however, as gene presence is a proxy for potential activity, but is not a final proof of the occurrence of ecologically significant process rates.

One of the reasons that it has been so difficult to quantify and characterize N cycling processes is that they are to a large extent controlled by indirect, biotic interactions. It is becoming increasingly clear that ecological interactions play a major role in the terrestrial N cycle. The realization that, and the observation that global change may alters the nature and timing of biotic interactions and thereby their effects on the N cycle only increases the need for their study warrants a better understanding of such effects (Díaz et al., 1998; Chapin et al., 2000). (Díaz et al., 1998; Chapin et al., 2000). In some ecosystems, N inputs to terrestrial ecosystems are dominantly mediated by mutualistic associations between plants and specific N-fixing microbial groups (Batterman et al., 2013a). More generally, plant species have an overarching impact on soil N cycling by directly mediating energy and material fluxes to soil microbial communities and/or by altering abiotic conditions that regulate microbial activity. For example, the type of mycorrhizal fungi that colonizes the plant root has been shown to correlate with organic N depolymerisation as fungal groups produce a specific set of enzymes. Also soil fauna have both a direct and indirect role in the soil N cycle as grazing activities may strongly affect microbial N release as well as alter soil physical properties. The fact that all these ecological interactions have a high degree of specificity and sensitivity to global change, which increases the probability that a change in the loss of a given plant-, microbial- or faunal species, or a change in their community composition, will have cascading effects on the rest of the system and ultimately impact on the overall soil N cycle (Chapin et al., 2000). (Chapin et al., 2000).
Here, we review important insights with respect to the soil N cycle that have been made over the last decade, and present our view on the key challenges for future soil research (Fig. 1).

The approach adopted in this paper is three-fold:

1. To identify and critically review specific N transformation pathways related to the production of N\textsubscript{2}O and N\textsubscript{2}. Here we focus on nitrifier denitrification (Section 2.1), which is a potentially important source of N\textsubscript{2}O; and N\textsubscript{2}O reduction (Section 2.2), the important but little-understood final step of denitrification. We focus exclusively on these two processes as we believe that sufficient literature information is available to demonstrate that these processes are key unknowns with respect to the emission rates of gaseous N forms. Additionally, we end the section on processes with discussing challenges with respect to measuring denitrification hot-spots and hot-moments of denitrification (Section 2.3).

2. To present methodological developments on \textsuperscript{15}N tracing models that should further aid studies on the production of gaseous N forms in soils (Section 3); and

3. To review mechanisms on how ecological interactions impact on soil N cycling. Specifically, we focus on soil faunal effects (Section 4.1), plant root controls (Section 4.2), mycorrhizal symbioses (Section 4.3), and biological N fixation (Section 4.4). Although other nutrient cycles can have strong effects on all aspects of the N cycle (e.g. Baral et al., 2014), we consider stoichiometric relations to be mostly outside the scope of this paper and do not exhaustively review them.

Although all authors agree with the contents of the final manuscript paper, however, some freedom has been given to express a somewhat personal view on developments within our respective fields of expertise (see Author Contribution section). This paper is not meant as a comprehensive literature review of soil N cycling research in the past. Instead, we have tried to
be judicious with respect to referencing older studies, only citing some key papers and focusing instead on more recent work. As such, we hope that our paper will spark discussion and inspire further research on the elusive aspect of soil N cycling.

The eight topics challenges which we address encompass basic processes (Section 2), proximal controls the effect of ecological interactions (Section 3) and methodology (Section 4). With regard to processes, we first (Section 2.1) focus on BNF in natural systems, especially discussing uncertainties with respect to free-living N\textsubscript{2} fixers. Subsequently (Sections 2.2 and 2.3) we discuss two elusive pathways: important but elusive pathways; nitrifier denitrification (Section 2.2) which is a potentially important source of N\textsubscript{2}O, and N\textsubscript{2}O reduction (Section 2.3), the important but little-understood final step of denitrification. We end the section on processes with discussing challenges with respect to measuring denitrification hot spots and hot moments (Section 2.4). We then focus on the effect of ecological interactions proximal controls, starting with the effects that soil fauna can exert on the N cycle through trophic interactions and ecosystem engineering (Section 3.1). We then discuss effects of proximal controls by plant roots and litter deposition (Section 3.2) as well as by different mycorrhizal symbioses on N transformations (Section 3.3). We end with discussing advanced stable isotope modeling tools to better understand gross N transformations (Section 4).

This paper is not meant as a comprehensive literature review of soil N cycling research in the past. Instead, we have tried to be judicious with respect to referencing older studies, only citing some key papers and focusing instead on more recent work with the aim of stimulating debate with respect to the current soil N research agenda.
2. Emerging insights on specific N cycling processes

2.1. N₂ fixation

An important share of bioavailable N enters the biosphere via biological fixation of atmospheric N₂ (BNF) (Vitousek et al., 2013). Biological N fixation can be natural (e.g., N₂ fixing trees that are present in forest ecosystems) or anthropogenic (e.g., N₂ fixation by leguminous agricultural crops). Two types of BNF, both using the nitrogenase enzyme, are present in nature: symbiotic N₂ fixation (S-BNF) and free-living N₂ fixation (F-BNF). Symbiotic N₂ fixation is here defined as the infection of plant roots by bacteria—such as *Rhizobia*, *Bradyrhizobia* or actinomycetes—followed by the formation of nodules. All other forms of BNF are regarded as free-living N₂ fixation (including e.g., fixation by bacteria in soil and litter, but also N fixation in lichens) (Reed et al., 2011).

Nitrogen demand in young successional tropical forest is high. The large fraction of leguminous plant species that forms symbiosis with N₂-fixing bacteria has recently been identified as a key element of functional diversity to overcome ecosystem-scale N deficiencies in tropical forest successions (Batterman et al., 2013a). Symbiotic fixation is thus considered to relieve N limitations and safeguard forest regrowth and CO₂-accrual as an ecosystem service. Nevertheless, S-BNF has also been postulated as the reason why mature tropical forest, having a lower N demand than early succession stands, become relatively rich in N and as a consequence loose (sometimes large amounts of) bioavailable N (Hedin et al., 2009) via NO₃⁻ leaching (e.g., Brookshire et al., 2012) or gaseous N loss (e.g., Werner et al., 2007).
However, a plant-level physiological perspective counters this assumption, as numerous experiments have shown that symbiotic S-BNF by leguminous species is mostly facultative and down-regulated when located in an N-rich environment. Tropical leguminous species thus have the potential to fix atmospheric N\textsubscript{2}, but it is likely that they only do so actively in young forest successions or disturbed ecosystems, and far less in mature forests. Secondly, only a part of the Fabaceae family have nodule forming capacities (mainly belonging to the Mimosoideae and Papilionoideae subfamilies). This consideration decreases the omnipresence and abundance of potential N-fixers in tropical forests, making their role as a vital chain in the tropical N-cycle less credible. Therefore, Hedin et al. (2009) have suggested a possible mechanism for explaining this tropical N paradox via a ‘leaky nitrostat model’ (Fig. 2). This concept brings forward the importance of F-BNF, which is hypothesized to take place, even in N-rich ecosystems, in localized N-poor microsites, such as litter layers, topsoil, canopy leaves, lichens or bryophytes on stems, etc. Combined, these free-living N\textsubscript{2} fixers would bring high amounts of N in the system, resulting in high N availability. However, spatially explicit data are virtually absent and largely based on geographically biased, indirect measurements using the acetylene reduction assay rather than direct \textsuperscript{15}N\textsubscript{2}-incubation measurements.

A recent spatial sampling method to assess total BNF indicated that tropical forest BNF is likely much lower than previously assumed (Sullivan et al., 2014). These authors reported mean rates of total BNF in primary tropical forests of 1.2 kg N ha\textsuperscript{-1} yr\textsuperscript{-1}, while previous empirical or modeled data ranged between 11.7 and 31.9 kg N ha\textsuperscript{-1} yr\textsuperscript{-1}. Secondary successional forests, as mentioned above, had higher total BNF than primary forest (6.2—14.4 kg N ha\textsuperscript{-1} yr\textsuperscript{-1}). Sullivan et al. (2014) proposed a time-integrated total BNF rate of 5.7 kg N ha\textsuperscript{-1} yr\textsuperscript{-1} for primary forest in Costa Rica, of which 20-50% is attributed to S-BNF. It remains to be shown whether this BNF
rate from primary tropical forest and proportions between S-BNF and F-BNF are valid for the
pan-tropics. But if total BNF in tropical forests is indeed much lower than previously thought,
this will fundamentally alter our assessment of tropical forest N cycles and the relative
correlation of anthropogenic inputs (Sullivan et al., 2014). There is indeed emerging evidence
that anthropogenic N deposition in tropical ecosystems is more substantial than assumed, as a
result of biomass burning, dust and biogenic deposition (Chen et al., 2010; European
Commission Joint Research Center, 2014; Cizungu et al., unpublished data). Hence, the relative
contribution of human perturbation (e.g. wild fire, livestock fossil fuel combustion) to the
tropical N cycle is likely much larger and warrants careful attention, e.g., by increasing N
deposition measurement networks in tropical forests (Matson et al., 1999). Moreover, there is
only limited understanding of the effects of proximate (N-, P- and Mo-availability) controls
(Barron et al., 2009; Wurzburger et al., 2012; Batterman et al., 2013b), and the impact of global
change factors (temperature, moisture, N-deposition) on F-BNF.

Finally, F-BNF also plays a role in the N cycle in some non-tropical ecosystems. In
boreal forests, symbiosis between cyanobacteria and feather mosses provides an important N-
input (DeLuca et al., 2002; Gundale et al., 2012). In peatlands, which contain approximately 30%
of global soil carbon, *Sphagnum* mosses living in close association with methanotrophic bacteria,
which can stimulate BNF by the phototrophic (through elevated CO₂ levels) and methanotrophic
bacteria themselves (Larmola et al., 2014). (Elbert et al., 2012; Keymer and Kent, 2014)

While large uncertainties exist regarding the temporal and spatial variability, dominant
determinants, and the magnitude and impact of BNF on terrestrial ecosystems functions and
services; even less is known regarding its future trajectories in view of global change. In several
relatively nutrient poor ecosystems, BNF is a vital process, which is poorly understood at the
ecosystem level. Characterizing these processes as well as gaining insight into their response to
global change needs further investigation.

2.21. Nitrifier denitrification

The study of nitrifier denitrification as a significant biogeochemical N₂O-producing process in
soils has been severely hampered by two persistent problems: one related to terminology, the
other to methodology.

With respect to terminology, it took a landmark paper (Wrage et al., 2001) to clearly
identify nitrifier denitrification as a distinct pathway for N₂O production, as it was often
confused- or combined with two other N₂O production pathways: nitrifier nitrification and
nitrification coupled denitrification (which is actually a combination of two classical processes
rather than a novel one: nitrifier nitrification followed by classical denitrification; Fig. 32).
Nitrifier denitrification is the production of N₂O by autotrophic ammonia oxidizing bacteria by
reduction of NO₂⁻. The process is therefore carried out by the same organisms that can produce
N₂O through nitrification. However, the two N₂O producing pathways are fundamentally
different; during nitrification N₂O is formed as a byproduct of a chemical process: the
spontaneous oxidation of one of the intermediate nitrogen species (hydroxylamine). Nitrifier
denitrification, on the other hand, is a stepwise reduction controlled by enzymes during which
N₂O is one of the intermediate products that might escape to the atmosphere. In fact, the
enzymes responsible for this stepwise reduction during nitrifier denitrification are remarkably
similar to those of canonical denitrification (possibly due to lateral gene transfer); they do not
appear to differ phylogenetically from NiR and NOR found in denitrifying organisms (Casciotti and Ward, 2001; Garbeva et al., 2007).

Despite the similarity with classical denitrification, there are good reasons to assume that nitrifier denitrification is controlled by different factors and should therefore be considered a distinct source of N\textsubscript{2}O emissions from soil. The main reason for this is that denitrifiers are heterotrophic, whereas ammonia oxidizing bacteria are chemo-autotrophic. It is not entirely clear yet why ammonia-oxidizing bacteria perform nitrifier denitrification. One hypothesis is that it is a response to NO\textsubscript{2}- toxicity under marginally aerobic conditions (Shaw et al., 2006).

Alternatively, the energetic gain from coupling NH\textsubscript{4}+ oxidization to NO\textsubscript{2}- reduction is similar to that from using O\textsubscript{2}, making nitrifier denitrification energetically attractive under marginally aerobic conditions (Shaw et al., 2006).

The process was described by early pure culture studies in the 1960s and 1970s (Hooper, 1968; Ritchie and Nicholas, 1972). Since then, it has been reported several times (e.g. Poth and Focht, 1985; Schmidt et al., 2004), but always in pure cultures. Despite suggestions that nitrifier denitrification could be an important contributor to soil N\textsubscript{2}O emissions (Granli and Bøckman, 1994; Webster and Hopkins, 1996), and that conventional methods of “nitrification N\textsubscript{2}O” measurements such as \textsuperscript{15}N tracing or inhibition with O\textsubscript{2} or acetylene might actually include nitrifier denitrification (Granli and Bøckman, 1994; Mosier et al., 1998), proof of its occurrence in actual soils has remained elusive.

The main challenge to evaluating the importance of nitrifier denitrification in soils is methodology. As the N in N\textsubscript{2}O produced from both nitrification and nitrifier denitrification originates from the same NH\textsubscript{4}+ pool, it is impossible to distinguish between these two processes with conventional \textsuperscript{15}N tracing methods (Stevens et al., 1997) alone. Methods using inhibition of
specific steps of (de)nitrification were proposed as a method to quantify nitrifier denitrification (Webster and Hopkins, 1996), but a series of studies showed that inhibition was unreliable due to problems with effectiveness and selectivity (Tilsner et al., 2003; Beaumont et al., 2004; Wrage et al., 2004a; Wrage et al., 2004b).

Various efforts have been undertaken to employ advanced stable isotope analysis to determine the contribution of nitrifier denitrification as an N₂O source. Sutka et al. (2006) suggested that the intramolecular distribution of ¹⁵N within the asymmetrical N₂O molecule (site preference) might be employed. In monoculture-pure culture studies, they showed that the site preference signature of nitrifier denitrification and denitrification differed significantly from that of classical nitrification (Sutka et al., 2006) as well as fungal denitrification (Ostrom and Ostrom, 2011). However, in a recent assessment Decock and Six (2013) concluded that huge challenges remain (related to process rates, heterogeneity, unaccounted-for processes, among others) before such an analysis can be reliably applied to soils. They conclude that analysis of site preference will likely remain a qualitative indicator of mechanisms underlying N₂O emissions, and recommend more studies to systematically characterize variation in site preference as a function of ecosystem, soil parameters as well as biogeochemical processes. Such studies are currently being conducted (e.g. Koster et al., 2013; Lewicka-Szczebak et al., 2014; Yano et al., 2014).

Wrage et al. (2005) proposed an alternative method based on artificially enriched stable isotope tracing. They combined ¹⁵N with ¹⁸O tracing to isolate nitrifier denitrification, utilizing the fact that all O in nitrifier-derived N₂O originates from O₂, but half of the O from nitrifier denitrification is derived from H₂O. However, their method, employing ¹⁸O-enriched H₂O as well as ¹⁵N-NO₃⁻ and ¹⁵N-NH₄⁺, did not take into account O exchange between H₂O and intermediates of the (de)nitrification pathways (Kool et al., 2007; Kool et al., 2009). This
exchange can be quantified using $^{18}$O labelled NO$_3^-$ (Kool et al., 2010; Kool et al., 2011b). With the help of a revised method, Kool et al. (2011a) showed that nitrifier denitrification exceeded "classical nitrification" as a dominant source of NH$_4^+$-derived N$_2$O emission, and was a dominant pathway of total N$_2$O production at low and intermediate soil moisture contents. Other studies using this method have confirmed that nitrifier denitrification was indeed the dominant pathway for NH$_4^+$ derived N$_2$O emissions (Zhu et al., 2013).

With terminology established and a method developed, nitrifier denitrification is now ready to be studied in detail in soils. However, methodological constraints still exist, as the dual isotope method is elaborate and includes a relatively large number of assumptions. These constraints will have to be addressed in the future.

### 2.23. Nitrous oxide consumption

Both net atmospheric and *in situ* N$_2$O consumption occur in the soil, reducing both atmospheric lifetimes of N$_2$O and net N$_2$O effluxes. Consumption of N$_2$O is enzymatically and energetically feasible. Net atmospheric consumption of N$_2$O has been sporadically reported for several terrestrial ecosystems, but mostly for wetlands and peatlands. Net consumption of atmospheric N$_2$O is enzymatically and energetically feasible. Consumption of N$_2$O has been sporadically reported for several terrestrial ecosystems, but mostly for wetlands and peatlands. A recent review by Schlesinger (2013) reports a net N$_2$O uptake range of $<1 - 207$ μg N m$^{-2}$ h$^{-1}$, but almost all uptake fluxes fall between 1 and 10 μg N m$^{-2}$ h$^{-1}$, with a median of 4 μg N m$^{-2}$ h$^{-1}$. The latest IPCC report (Stocker et al., 2013) mentions a global surface N$_2$O sink of 0 – 1 Tg N$_2$O-N
Another recent review (Majumdar, 2013) reported in situ N₂O consumption rates in rice fields ranging from 0.13 - 191 μg N m⁻² h⁻¹. For that purpose, Yang et al. (2011) developed an ¹⁵N₂O isotope dilution method that allows for calculation of gross N₂O production and consumption rates. These authors observed a relative N₂O yield of 0.84, indicating that 16% of the gross N₂O production was consumed in situ. Hence, both net atmospheric and in situ N₂O consumption occurs in soil reducing both atmospheric lifetimes and net N₂O effluxes. However, Well and Butterbach-Bahl (2013) question the validity of the latter experimental approach. The latest IPCC report (Stocker et al., 2013) mentions a global surface N₂O sink of 0 – 1 Tg N₂O-N yr⁻¹. This sink strength is not sufficient to explain the imbalance between global N₂O sources and sinks (Schlesinger, 2013). Understanding the role of in situ N₂O reduction for attenuation of the net soil N₂O release warrants careful attention because of a recently identified microbial guild capable of N₂O reduction (Sanford et al., 2012) (Sanford et al., 2012).

Based on recent evidence from the literature we have identified three possible routes for N₂O consumption. First, in addition to the ‘typical‘ nitrous oxide reductase (nosZ I) that reduces N₂O during denitrification, a recently identified microbial guild is suggested to mediate the soil N₂O sink (Sanford et al., 2012; Jones et al., 2014). Newly discovered non-denitrifier, ‘atypical’ N₂O reductase (nosZ II) gene diversity and abundance potentially play a significant role in N₂O consumption in soil. Orellana et al. (2014) indicated that ‘atypical’ nosZ outnumber typical nosZ in soil.

Second, some bacteria that perform dissimilatory nitrate reduction to ammonia (DNRA) are capable of N₂O reduction to N₂ as they carry a nos gene encoding for N₂O reductase (N₂OR) (Simon et al., 2004). Mania et al. (2014) indicated that, depending on the environmental
conditions, these bacteria may reduce N\textsubscript{2}O that is provided by other bacteria or that they produced themselves as a by-product during DNRA.

Third, there is evidence that both direct assimilatory N\textsubscript{2}O fixation via nitrogenase (Vieten et al., 2008; Ishii et al., 2011; Farias et al., 2013) or indirect N\textsubscript{2}O fixation via a combination of N\textsubscript{2}O reduction and N\textsubscript{2} fixation can account for N\textsubscript{2}O consumption. Itakura et al. (2013) showed that inoculation of soil grown with soybean with a non-genetically modified mutant of *Bradyrhizobium japonicum* with a higher N\textsubscript{2}O reductase activity (nosZ++) reduced N\textsubscript{2}O emission. In farm-scale experiments on an Andosol, an N\textsubscript{2}O mitigation of ca. 55% was achieved with such inoculation. Desloover et al. (2014) identified a *Pseudomonas stutzeri* strain that was able to grow on N\textsubscript{2}O as the only source of N and electron acceptor. *Pseudomonas stutzeri* is known to possess both nitrogenase and nitrous oxide reductase (nosZ I) (Pomowski et al., 2011). A \textsuperscript{15}N labelling study showed that N\textsubscript{2}O is immobilized into microbial biomass via N\textsubscript{2}O reduction to N\textsubscript{2} followed by re-uptake of the released N\textsubscript{2} and subsequent fixation into NH\textsubscript{4}\textsuperscript{+} via nitrogenase (Desloover et al., 2014).

In conclusion, five possible pathways for N\textsubscript{2}O consumption have been identified (Fig. 43):

1. dissimilatory N\textsubscript{2}O reduction to N\textsubscript{2} via typical, denitrifier nosZ I,  
2. atypical, non-denitrifier nos Z II,  
3. during DNRA that produces N\textsubscript{2}O\textsubscript{0} as a by-product,  
4. direct assimilatory N\textsubscript{2}O fixation via nitrogenase to NH\textsubscript{3}, and  
5. indirect assimilatory N\textsubscript{2}O fixation (N\textsubscript{2}O reduction to N\textsubscript{2} followed by N\textsubscript{2} fixation). Clearly, NO\textsubscript{3}\textsuperscript{−} reduction in soil is handled by a network of actors (Kraft et al., 2011) and has a more modular character than the classical linear presentation of denitrifying enzymes suggests (Simon and Klotz, 2013). Moreover, a high degree of metabolic versatility is observed for many organisms; genes encoding for denitrification, DNRA, and atmospheric N fixation have, for instance, been found in a single bacterial species (Simon, 2002;
Finally, Verbaendert et al. (2014) showed that molecular tools that have been developed to identify denitrifying bacteria are biased towards Gram-negative denitrifiers. Hence, we propose that the analysis of expression of novel, recently discovered genes involved in N₂O consumption in conjunction with quantification of N₂O fluxes in various soil types is required to advance our understanding of microbial and physicochemical controls on N₂O consumption, and ultimately to develop improved biogeochemical models of soil N₂O sink function towards gram-positive denitrifiers. Hence, we propose that assessment of novel gene expressions in conjunction with the quantification of N₂O consumption in various soil types is required to advance our understanding of microbial and physicochemical controls on N₂O consumption, and ultimately to develop improved biogeochemical models of soil N₂O sink function.

2.34. Denitrification

Perhaps the most poorly understood process in the N cycle is denitrification, the anaerobic microbial conversion of the nitrate (NO₃⁻) and nitrite (NO₂⁻) to the gases nitric oxide (NO), nitrous oxide (N₂O) and dinitrogen (N₂) (Seitzinger et al., 2006; Groffman, 2012) is an extremely challenging process to measure. This process is of great interest because it can significantly reduce pools of reactive N (and thus productivity) in ecosystems and because NO₃⁻, NO and N₂O cause diverse air and water pollution problems (Davidson et al., 2012). Denitrification is difficult to quantify because of problematic measurement techniques (especially for its end product N₂), high spatial and temporal variability, and a lack of methods for scaling point measurements to larger areas (e.g. Groffman et al., 2006). A particular challenge is the fact that small areas (hotspots) and brief periods (hot moments) frequently account for a high percentage of N gas.
flux activity, and that it is increasingly recognized that denitrification is in many ways a modular rather than a singular process. This presents a variety of problems related to measurement, modelling and scaling (Groffman et al., 2009). Global mass balance analyses (Seitzinger et al., 2006) suggest that the biggest global sink for anthropogenic N must be terrestrial denitrification, yet there are few direct measurements to support these results. Modelling efforts estimate that global N₂ production from denitrification may increase from 96 Tg yr⁻¹ in 2000 to 142 Tg yr⁻¹ in 2050 due to increased N inputs in the global agricultural system (Bouwman et al., 2013).

Questions about “missing N” and denitrification are particularly dramatic and compelling in agricultural ecosystems, landscapes and regions, where most industrially derived N is applied and the opportunity for large terrestrial denitrification fluxes exists.

Addressing the challenge of denitrification requires advances in three main areas; 1) improved methods for quantifying N gas fluxes (see also section 2.2); 2) experimental designs that incorporate hotspot and hot moment phenomena; and 3) approaches for temporal and spatial scaling that account for hotspot and hot moment phenomena at multiple scales.

Denitrification has always been a challenging process to measure (Groffman et al., 2006), primarily due to the difficulty of quantifying the flux of N₂ from soil against the high natural atmospheric background of this gas (Yang and Silver, 2012; Yang et al., 2014). Most denitrification methods therefore involve alteration of physical or chemical conditions through the use of inhibitors (e.g., acetylene) or amendments (e.g., ¹⁵N) that produce inaccurate or unrealistic estimates of rates. However, there have been recent advances in methods for quantifying N₂ flux and in isotope-based methods that provide area and time-integrated denitrification estimates that are more relevant to ecosystem-scale questions.
Our understanding of the N$_2$ flux associated with denitrification has been improved at least somewhat by the development of soil core-based gas recirculation systems that involve replacement of the natural soil N$_2$/O$_2$ atmosphere with a He/O$_2$ atmosphere, followed by direct measurement of N$_2$ and N$_2$O production as well as their ratio (Swerts et al., 1995; e.g. Wang et al., 2011; Kulkarni et al., 2014). It is important to note that these new methods are based on extracted soil cores, incubated over extended periods, which can create artificial conditions (Frank and Groffman, 2009). However, some confidence in the flux estimates from cores can be developed by comparing estimates of CO$_2$ and N$_2$O fluxes in the cores and in situ field chambers.

The new soil core incubation systems, along with new soil O$_2$ sensors, have also advanced our understanding of hot moments of denitrification. Because it is possible to vary the O$_2$ concentration of the recirculation stream in the new incubation systems, denitrification versus O$_2$ relationships can be established and linked with continuous estimates of soil O$_2$ from the new sensors to produce continuous estimates of flux (Burgin and Groffman, 2012; Duncan et al., 2013). Recent studies have shown that these relationships are more complex than previously thought. For example, in northern hardwood forests in north-eastern North America, denitrification rates have been found to be higher at 5% or 10% O$_2$ than under completely anaerobic conditions, suggesting that there is tight coupling between NO$_3^-$ production by nitrification and denitrification in these soils (Morse et al., 2014a).

As our ability to quantify denitrification has improved, our understanding of the factors that control the occurrence of hotspots and hot moments of activity has also increased. Riparian zones have been studied in this regard for several decades (e.g. Lowrance et al., 1997; Mayer et al., 2007). This has resulted in efforts to protect and restore riparian zones to decrease N delivery to receiving waters in many locations. Still, there is great uncertainty about just how much N is
denitrified in riparian zones and through other N control practices, and how much N remains in the soils and vegetation of these areas where it is susceptible to later conversion back to NO$_3^-$ or N$_2$O (Woli et al., 2010).

More recently, there has long been recognition of the potential for hotspots and hot moments denitrification to occur within crop fields or pastures. Periods of transient saturation low in the soil profile can support significant amounts of denitrification that are missed in sampling programs that focus on surface soils (Werner et al., 2011; Morse et al., 2014b). Areas of wet soil, low soil O$_2$ and possibly high denitrification are also common at the transition between fall and winter and between winter and spring (Walter et al., 2000). Animal grazing and excretion can create hotspots of N deposition, mineralization, nitrification, denitrification and N$_2$O flux (de Klein et al., 2014).

Experiments incorporating new ideas about hotspots and hot moments can benefit from recent studies that have characterized diversity in denitrifying phenotypes that reflect adaptation to prevailing environmental conditions with consequences for denitrification activity (Bergaust et al., 2011). These ideas have the potential to improve these experiments by allowing for more mechanistic, hypothesis-driven approaches that underlie more "black-box" ideas based on proximal drivers of denitrification.

Estimates of denitrification produced by direct measurement in soil cores can be validated using isotope measurements and models. Shifts in $^{15}$N-NO$_3^-$ have been used to indicate denitrification in soils, riparian zones, agricultural streams, and large rivers (e.g. Kellman and Hillaire-Marcel, 1998; Vidon and Hill, 2004). Dual natural isotope ($^{18}$O- and $\delta^{15}$NO$_3^-$) analysis has been used to estimate denitrification in aquifers (Wassenaar, 1995), agricultural (Burns et al.,
2009) and urban (Kaushal et al., 2011) catchments as well as in tropical forest soils (Houlton et al. 2006).

The time is thus ripe for ecosystem, landscape and regional-scale studies of denitrification. We have new methods capable of producing well constrained estimates of denitrification at the ecosystem scale and new ideas about the occurrence of hotspots and hot moments at ecosystem and landscape scales. In combination with independent approaches for, and powerful new tools for extrapolation and validation of denitrification estimates, our estimates of this important process are likely to improve markedly over the next decade, at regional and continental scales.

3. $^{15}$N tracing modelling for understanding N cycling processes

This section will focus on how $^{15}$N enrichment in combination with process oriented modeling (Rütting et al., 2011b; Huygens et al., 2013) has helped to advance our understanding of N cycling dynamics in soils, and will be able to do so further in the future.

The stable isotope $^{15}$N has been used as a tracer for the quantification of gross N transformation rates for 60 years. In their two seminal papers Kirkham and Bartholomew (1954, 1955) developed the isotope pool dilution technique, enabling for the first time the quantification of gross transformation rates of N cycling processes. Quantification of gross rates has deepened our understanding of the terrestrial N cycle tremendously. For example, Davidson et al. (1992) showed that old-growth forests exhibit high gross mineralization rates, challenging the paradigm (based on net mineralization rate measurements) that these ecosystems have low mineralization activity. The isotope pool dilution technique is still widely used, even though it has some
important limitations. The most crucial disadvantage is that only total production and consumption rates of a labelled N pool can be quantified, which may be the result of several simultaneously occurring N processes (Schimel, 1996). For example, gross nitrification as quantified by the isotope pool dilution technique can be comprised of two separate processes, autotrophic (NH$_4^+$ oxidation) and heterotrophic (the oxidation of organic N to NO$_3^-$) nitrification. To overcome this limitation, $^{15}$N labelling can be done in conjunction with numerical $^{15}$N tracing models (Rütting et al., 2011b). These models describe the flow of N and $^{15}$N though the various soil N pools (e.g. NH$_4^+$, NO$_3^-$ and organic N), whereby transformations are represented by kinetic equations (e.g. zero- or first-order kinetics). The first $^{15}$N tracing model which could separate autotrophic from heterotrophic nitrification was presented by Myrold and Tiedje (1986).

Subsequent studies using $^{15}$N tracing models have shown that heterotrophic nitrification can be a significant or even the dominant NO$_3^-$ production pathway in forest and grassland soils (Barraclough and Puri, 1995; Rütting et al., 2008; Taylor et al., 2013). In addition, $^{15}$N tracing models have been shown to be useful for investigating the importance of DNRA in various soils (Rütting et al., 2011a). Moreover, they can be used to distinguish DNRA from alternative pathways such as remineralization and plant efflux (Burger and Jackson, 2004). Recently an $^{15}$N amino acid pool dilution approach has been developed (Wanek et al., 2010), which can be a useful tool for investigating whether depolymerization or N mineralization is the rate limiting step of the terrestrial N cycle (Schimel and Bennett, 2004), particularly if incorporated in numerical $^{15}$N tracing models.

In addition to quantification of gross N transformation rates, $^{15}$N enrichment has proven useful for partitioning nitrous oxide (N$_2$O) emission sources. Using a two-source mixing model, Stevens et al. (1997) investigated the contribution of NO$_3^-$ reduction (i.e. denitrification) and
NH₄⁺ oxidation (i.e. autotrophic nitrification) to N₂O emission. Subsequent work, however, suggested that organic N can be a third substrate for N₂O production. Indeed, ¹⁵N studies using a triplet tracer approach and either analytical (Stange et al., 2009) or numerical (Stange et al., 2013; Müller et al., 2014) ¹⁵N tracing models showed a significant or even dominant contribution of oxidation of organic N (heterotrophic nitrification) to N₂O production in soils. The numerical models have the additional advantage that gross N₂O production rates can be quantified. Using oxygen isotopes (¹⁸O) as an additional tracer allows the separation of NH₄⁺ derived N₂O emission between NH₄⁺ oxidation and nitrifier-denitrification (Kool et al., 2011a). The limitations and opportunities of this approach are discussed in Section 2.1. A further step for understanding sources of N₂O emission from soil would be to incorporate ¹⁸O into numerical tracing models, i.e. development of a combined ¹⁵N-¹⁸O-tracer model. Overall, stable isotope labeling approaches (¹⁵N and ¹⁸O) have greatly increased our understanding of the diverse N cycle processes contributing to N₂O production in soils. Moreover, these studies have confirmed the importance of NO₂⁻ dynamics for N₂O production (Stange et al., 2013; Müller et al., 2014) and for the soil N cycle in general (Rütting and Müller, 2008; Isobe et al., 2012).

### 34. Proximal Ecological interactions and controls of N cycling processes

#### 34.1. Soil fauna

Until recently, the influence of soil fauna other than humans on the soil N cycle in agroecosystems has been mostly neglected. Nitrogen transformation processes and -loss pathways have almost exclusively been related to the interplay between microbial dynamics in
the soil and abiotic factors. At first glance this seems logical: micro-organisms dominate the biomass of soil life to a large degree, and many conversions in the N cycle (e.g. nitrification, denitrification, nitrifier-denitrification, N fixation, DNRA) are the exclusive domain of micro-organisms. Biochemical as well as physical processes, such as nitrification and N leaching are controlled by abiotic factors (e.g. pH, porosity and temperature). In turn, both microbial dynamics and abiotic factors can be changed by human influences such as N deposition in natural systems and fertilization, liming, and soil tillage and animal husbandry in agricultural systems (Fig. 5a4a).

What important role do soil fauna then have in the N cycle? Like the effect of humans, their role can be dramatic but is essentially indirect: through trophic interactions and burrowing activities they may strongly affect microbial dynamics in the soil as well as soil physical properties (Fig. 5b4b).

The only part of the soil N cycle where the role of soil fauna has been reasonably well established is N mineralization and subsequent plant uptake. Soil fauna affects N mineralization by a combination of activities, including trophic interactions (grazing on micro-organisms, predation) as well as fragmentation of organic matter, mixing organic matter into the soil, excreting nutrient-rich compounds and dispersing microbial propagules (Bardgett and Chan, 1999).

In a literature study across natural and agricultural systems, Verhoef and Brussaard (1990) found a relatively stable faunal contribution to N mineralization of around 30%. Different functional groups of soil fauna, however, contribute to N mineralization differently, with the largest contributions provided by bacterial-feeding micro-fauna (nematodes and amoeba), followed by earthworms and potworms, and minor contributions by fungal-feeding nematodes.
and micro-arthropods (De Ruiter et al., 1993). Among meso- and macro-fauna, the role of earthworms has been most extensively studied (e.g. Postma-Blaauw et al., 2006; Van Groenigen et al., 2014). As "ecosystem engineers", they are well-known to affect soil structure and litter redistribution, thereby affecting many aspects of the N cycle as well as other soil processes (Shipitalo and Le Bayon, 2004; Blouin et al., 2013). In a recent meta-analysis, Van Groenigen et al. (2014) showed that in agricultural systems earthworms increase crop yield on average by 25%. This effect was consistent between different functional groups of earthworms, but increased with earthworm density and crop residue application rates. Because this beneficial effect disappeared with adequate N fertilization, it was mainly ascribed to increased N mineralization from crop residue and soil organic matter. In tropical ecosystems soil-feeding termites are known to have a similarly large impact on N mineralization (Ji and Brune, 2006). Termites are also able to volatilize ammonia from their gut as well as from their faeces. However, this has only been shown to lead to high NH₃ concentrations in their nest atmosphere. It is not yet clear whether the NH₃ accumulating in the internal nest atmosphere can escape into the ambient air (Ji and Brune, 2006).

The effect of faunal diversity rather than single faunal groups is complex. Combinations of functionally dissimilar soil fauna can increase the N-mineralization rate due to facilitative interactions (Heemsbergen et al., 2004). These include one group benefitting from the activity of another group, for example through changes in soil structure or litter shredding by isopods promoting microbial growth (Wardle, 2006). Yet, competitive interactions may also positively influence mineralization rates (Loreau, 1998). For instance, predatory mites in the soil feed on fungivorous mites and potworms as well as springtails and nematodes (De Ruiter et al., 1995), and can thereby influence microbial activities through trophic cascades (induced positive effects
on microbes by feeding on microbial feeders). Even though empirical evidence of such trophic cascades in soil food webs is scarce (Mikola and Setälä, 1998; Bardgett and Wardle, 2010), the presence of predatory mites can potentially influence the behavior of fungivorous mites and potworms in terms of their feeding rate and spatial distribution. Such interactions (both facilitative and competitive), within and across trophic levels, have not yet been explored for most N cycling processes, including N loss pathways.

Among the relatively few studies that have focused on processes other than N mineralization, earthworms are again by far the most studied group. They have been shown to affect microbial N immobilization (Brown et al., 1998) as well as nitrification and denitrification (e.g. Parkin and Berry, 1999; Rizhiya et al., 2007). A growing body of literature shows that earthworms can considerably increase N₂O emissions (Lubbers et al., 2013). A recent meta-analysis on the effect of earthworms on soil greenhouse gas emissions reported an average earthworm-induced increase in N₂O emissions of 42% (Lubbers et al., 2013). This was hypothesized to be the result of effects on the denitrifier community as well as changes in soil structure affecting gas diffusivity and anaerobicity (Drake and Horn, 2006; Drake and Horn, 2007; Nebert et al., 2011). Further work on soil microbiology and soil structure—molecular, work—is needed to determine what the exact effects are of earthworm activity on microbial producers and consumers of N₂O as well as on net soil N₂O emission. Molecular microbial analysis and soil X-ray tomography are state-of-the-art experimental techniques that may shed more light on the mechanisms behind earthworm effects on N₂O emission.

Evidence for involvement of other faunal groups in these processes is scarce. Potworms, phylogenetically related to earthworms and with similar foraging and burrowing habits (albeit at a smaller scale), have been recognized as vectors for microbial colonization (Rantalainen et al.,
High soil NO$_3$ levels in the presence of potworms have been linked to increased nitrification potential (Liiri et al., 2007). Recent work has shown that trophic interactions involving springtails, fungivorous mites and predatory mites can strongly affect N$_2$O emissions (Kuiper et al., 2013; Thakur et al., 2014), although the exact pathways remain unclear - both "real" trophic relations as well as altered behavior due to sensing of the presence of predators may play a role.

Changes in soil structure (porosity, aggregation) by faunal activity can affect soil physical processes as well. Burrowing activities of earthworms may create preferential flow pathways that increase leachate volume and consequently the total leaching loss of inorganic N and dissolved organic N (e.g. Dominguez et al., 2004). Interactions between other soil faunal species have received little attention with regard to their effects on soil physical properties. Smaller fauna such as potworms, springtails, mites and nematodes are often assumed to have negligible direct effects on larger-scale soil structure, because they are usually confined to pre-existing voids in litter or soil (Lee and Foster, 1991; Whalen and Sampedro, 2010). However, these small fauna can significantly alter soil microstructure by producing faecal pellets, and potworms can also increase soil porosity and pore continuity by their burrowing activity (Topoliantz et al., 2000; Van Vliet et al., 2004).

**Overall, soil biota are essential for maintaining healthy soils and providing ecosystem services, such as N mineralization and plant uptake for food, fuel and fiber production. However, it is not clear whether they are able to do so without creating detrimental effects on N loss pathways such as N leaching and N$_2$O emissions. Understanding the role of soil fauna in soil N research should therefore focus on potential trade-offs between the need to produce enough food, fuel and fiber on the one hand, and the need to mitigate global warming and avoid biodiversity**
loss due to eutrophication on the other. So far, mechanistic knowledge on the controlling factors for possible mitigation options is largely lacking. Addressing the question of how to reap the benefits of a diverse soil community while avoiding the drawbacks will provide fundamental insights that can be used to design future sustainable agricultural systems. Ultimately, the role of soil fauna, as so much else in the soil, is strongly determined by human activity. In agricultural fields, land management such as tillage can disturb the soil food web and shift soil food web composition by differential sensitivities of the soil fauna to tillage (Postma-Blaauw et al., 2012). Application of crop residues, manure or fertilizer can change the soil food web size and structure by the supply of easily available C and N in specific locations and at specific times (Fig. 5). Future efforts to model the effects of soil fauna on N dynamics will have to address both the direct effects of fauna as well as the indirect effects of soil management on faunal communities.

### 34.2. Rhizodeposition and plant traits

Soil microbial communities depend almost exclusively on plant derived resources for their energy and nutrient supply. For a long time, it was presumed that plant litter was the most relevant organic matter input for the soil food web, and that plant effects on soil biogeochemistry were mainly mediated via the indirect impacts of plant inputs on relatively inert soil properties. Therefore, most of our initial understanding of soil biogeochemistry was based on experiments with root-free soils.

The impact of spatially and temporarily dynamic processes occurring in the rhizosphere on N cycling has rarely been considered (Frank and Groffman, 2009; Rütting et al., 2011b). Nevertheless, an important share of the energy for microbial metabolism is delivered by
belowground plant parts through root exudation, cell sloughing, and root and mycorrhizal fungal turnover (Nguyen, 2003). Healthy growing roots pass a large proportion of the C they receive to the soil as root exudates. This includes a range of materials, but soluble compounds, consisting of organic acids, carbohydrates and amino acids comprise the largest component (Farrar et al., 2003). The total amount and composition of root exudates varies between plant species and genotypes, and is influenced by plant phenology and environmental conditions (Nguyen, 2003). Moreover, fine root turnover, caused by the production, mortality and decay of short-lived C-rich roots, is another key pathway of significant nutrient flux in terrestrial ecosystems that may equal or even exceed that of above-ground litter fall in certain ecosystems (Gill and Jackson, 2000; Yuan and Chen, 2010).

There are several mechanisms through which plant roots can affect rhizosphere N cycling (reviewed in Paterson, 2003; Dijkstra et al., 2013; Cheng et al., 2014). Rhizodeposition may enhance microbial growth and activity and stimulates production of microbial exoenzymes that mine for more complex soil organic N compounds, a process often referred to as "priming" (Paterson, 2003). Nitrogen immobilized by the microbial community may temporarily reduce soil N availability, but immobilized N can become available in the rhizosphere due to microbial turnover and the grazing of rhizosphere microorganisms by soil micro-fauna (See Section 34.1). The quality of rhizodeposition is an important determinant for soil microbial communities; any shifts in their composition may affect decomposition processes through the production of distinct sets of extracellular enzymes (Dennis et al., 2010; Kaiser et al., 2010). Nevertheless, under conditions of low N availability, plant N uptake may limit microbial substrate N availability and reduce microbial growth and decomposition activity (Dijkstra et al., 2010; Blagodatskaya et al., 2014). Moreover, the production of specific metabolites that act as signaling molecules could
accelerate or retard soil N cycling if they act upon certain functional microbial taxa (De-la-Pena and Vivanco, 2010). Finally, specific N cycling processes, such as denitrification or N fixation could be altered in the rhizosphere due to altered microbial substrate conditions, encompassing C, O_2 and NO_3^- availabilities (Philippot et al., 2009). Altogether, rhizodeposition mostly causes an increase in microbial activity and soil N decomposition compared to bulk soils. Nevertheless, nutrient availability in the rhizosphere and competitive interactions between plant and microbial communities may shift the magnitude and direction of N cycling processes. This holds especially true for those processes that are performed by phylogenetically less diverse microbial functional groups; processes such as nitrification and methane uptake should therefore be much more sensitive to shifts than N mineralization. Nevertheless, nutrient availability in the rhizosphere and competitive interactions between plant and microbial communities may shift the magnitude and direction of N cycling processes, especially those processes performed by phylogenetically less diverse microbial functional groups, such as nitrification and denitrification (Philippot et al., 2009; Dijkstra et al., 2013).

Although the quality and quantity of rhizodeposits clearly influence rhizosphere N cycling, a major challenge lies in determining to what extent plant community characteristics explain the observed variations of rhizosphere impacts (Cheng et al., 2014). Considering the great difficulties in assessing rhizodeposition under field conditions (Pausch et al., 2013a), a prospective approach may involve measuring ‘soft’ plant traits that are relatively easy to observe and quantify (Fry et al., 2014). There are several traits that are good candidates due to their putative intimate relationship with rhizodeposition. For example, root exudation is linked to the intensity of canopy photosynthetic activity and photo-assimilate supply (Kuzyakov and Cheng, 2001). Fast-growing, acquisitive plants with high specific leaf area and short life span are thus
thought to be associated with a larger rhizosphere effect (Wardle et al., 2004). Because root exudation is concentrated at the apices of the roots and at the nodes where lateral roots emerge (Jaeger et al., 1999), root architectural traits determine the expansion of the rhizosphere and exudate fluxes per unit of root biomass. A densely branched root system with high biomass and a rapid turnover thus contributes large quantities of exudates (Van der Krift et al., 2001). The chemistry of rhizodeposits is a key controlling variable of rhizosphere dynamics, as microbial communities may shift their N use efficiency in response to substrate stoichiometry, leading to changes in soil N cycling fluxes (Moorshammer et al., 2014).

Several studies have examined presumed relationships between N cycling parameters and plant traits, especially of aboveground plant organs (e.g. Wedin and Tilman, 1990; Orwin et al., 2010; Garcia-Palacios et al., 2013; Grigulis et al., 2013). Soil N cycling processes appear to be primarily driven by traits of the most abundant species (the biomass ratio hypotheses; Grime, 1998), although complex effects may arise due to interspecies interactions and non-additive species effects (Grigulis et al., 2013; Pausch et al., 2013b). These studies confirm that plant characteristics, including under-investigated root traits, exert a key control over soil microbial communities, and modify the fundamental physiologies that drive soil N cycling. Nevertheless, the lack of clear-cut relationships between specific plant traits and N cycling parameters indicates the necessity for more research on plant communities to establish consistent links between plant traits and N cycling variables, especially under field conditions. Understanding such relationships will lead to improved upscaling capabilities, and perhaps ultimately the inclusion of rhizosphere effects in biogeochemical models.
34.3. Mycorrhizal associations

This section will focus on the extent to which the main types of mycorrhizal symbioses, arbuscular mycorrhiza and ectomycorrhiza, differentially affect the soil N cycle. Early conceptual models linked the replacement of arbuscular mycorrhizal plants by ectomycorrhizal plants to succession (Read, 1991) or to latitudinal and altitudinal gradients from warmer to colder climates (Read and Perez-Moreno, 2003). This was considered to be driven by shifts from P to N limitation and from mainly inorganic to more organic nutrients cycles. This was considered to be driven by shifts from P to N limitation, where simultaneously an increasing fraction of the N and P was present in organic forms to which ectomycorrhizal fungi were supposed to have better access than arbuscular mycorrhizal fungi. However, Dickie et al. (2013) noted a poor fit between these models and actual data on primary succession and suggested that nutrient limitation shifts from N- to P-limitation in retrogressive succession. Although a new model of general applicability has not yet been proposed, the underlying idea of a fundamental difference between arbuscular mycorrhiza-dominated ecosystems with more open, inorganic nutrient cycles and ectomycorrhiza-dominated ecosystems with more closed, organic nutrient cycles has persisted, especially for forests in temperate regions (Phillips et al., 2013; Bradford, 2014). We note that the same distinction was proposed between bacterial- and fungal-dominated agro-ecosystems by De Vries and Bardgett (2012). Their conceptual model is apparently not applicable for the tropics, where both arbuscular mycorrhizal and ectomycorrhizal forests are characterized by an open N cycle (Kuyper, 2012; Tedersoo et al., 2012). This geographical contrast raises the question to what extent the nature of the mycorrhizal symbiosis is causally relevant for differences in forest ecosystem functioning, or whether plant traits other than the mycorrhizal symbiosis cause these differences. Arguments that the mycorrhizal symbiosis is
causally relevant for soil N cycling are connected to the claim that ectomycorrhizal fungi, contrary to arbuscular mycorrhizal fungi, possess extensive saprotrophic activity are therefore able to make mN available in the soil ("mining")ine for N (Koide et al., 2008; Talbot et al., 2008), and therefore could access organic sources of N and phosphorus.

Several authors have compared uptake of various amino acids by arbuscular and ectomycorrhizal plants. The ability to depolymerize large N-containing molecules (proteins) into smaller fragments that can be taken up (Schimel and Bennett, 2004) and the ability to increase access to these large molecules, which are often bound to phenolics and other recalcitrant compounds, have been mainly studied for ectomycorrhizal fungi. Talbot and Treseder (2010) demonstrated widespread ability among ectomycorrhizal fungi to take up amino acids and noted that the relative benefit of the symbiosis was largest for the most common amino acids. Arbuscular mycorrhizal fungi also have widespread ability to take up amino acids (Whiteside et al., 2012). Arbuscular mycorrhizal plants took up significantly larger amounts of eight amino acids (phenylalanine, lysine, asparagine, arginine, histidine, methionine, tryptophan, and cysteine) than non-mycorrhizal plants and significantly smaller amounts in the case of aspartic acid. Contrary to the hypothesis by (Talbot and Treseder, 2010) Talbot and Treseder (2010) for ectomycorrhizal plants, the authors noted that the mycorrhizal effect on uptake was inversely related to the abundance of that amino acid in the database of all known proteins. The authors speculated that preferential use of rare amino acids by arbuscular mycorrhizal plants may reduce competition with ectomycorrhizal plants for amino acids; however, the arbuscular mycorrhizal benefit is largest with the least common amino acids. The authors hypothesized that these contrasting patterns of amino acid use may reduce competition for rare amino acids. However, the extent to which this form of niche differentiation would reduce competition depends on the
rate at which amino acids become available in the soil solution and hence to what extent the two preceding steps (increased access to protein-phenolic complexes; depolymerization of proteins) are rate-limiting. It is therefore necessary to assess the mycorrhizal role in those two steps.

Lindahl et al. (2007) showed an increased C:N ratio in deeper humus layers, and this effect was attributed to selective N mining by ectomycorrhizal fungi. Several studies have provided explicit support that ectomycorrhizal fungi can mine humus layers for N and have identified the relevant ectomycorrhizal fungi (Hobbie et al., 2013; Rineau et al., 2013; Bödeker et al., 2014). Wu (2011) on the other hand claimed that direct access by ectomycorrhizal fungi to N from the protein-polyphenol complex is likely limited and attributed a major role for interactions between saprotrophic and ectomycorrhizal fungi. Current evidence suggests that arbuscular mycorrhizal fungi have neither the ability to degrade humus for N-rich compounds nor the ability to depolymerize proteins into amino acids. The widespread ability of arbuscular mycorrhizal fungi to take up amino acids may therefore not be related to closed nutrient cycles with a major role for uptake of organic nutrients, but may rather function as a scavenging mechanism to re-absorb exudates, including amino acids. More information about the role of arbuscular mycorrhiza in the uptake of organic N is provided in recent reviews by Veresoglou et al. (2012) and Hodge and Storer (2014).

The stable isotope $^{15}$N has been used to study the role of mycorrhizal symbioses in accessing different N pools. Whereas early studies had examined the congruence between the $^{15}$N signal of a potential N source and that of mycorrhizal fungi as evidence for uptake from that source, recent studies have emphasized the importance of N partitioning between fungus and plant (fractionation of N-depleted chitin or enriched proteins that are transferred to the plant) as a major control of isotopic composition (Hobbie and Högberg, 2012). Both the ability to take up N
from organic sources (proteolytic fungi) and a relatively large transfer from fungus to plant are consistent with $^{15}$N enrichment of ectomycorrhizal fungi. Both mechanisms are likely correlated as fungi in more N-limited sites transfer relatively more N per unit C at the symbiotic interface. Further study of both traits is needed to better understand ectomycorrhizal fungal isotopic signatures, and especially cases of extreme enrichment (up to 20‰) where the nature of the N source is unknown.

A corollary of the conceptual model of Phillips et al. (2013) and of earlier models is that arbuscular mycorrhizal and ectomycorrhizal plants differ in their carbon and nutrient cycling traits (decomposability and nutrient release). Data by Cornelissen et al. (2001) were consistent with that prediction, showing that the mycorrhizal trait is a predictor for the so-called "fast – slow" spectrum (Reich, 2014). However, the comparison involved plant species that are not only different with regard to the mycorrhizal trait but also with regard to a number of other traits. Koele et al. (2012) applied phylogenetic correction, by comparing sister clades that differed only in their mycorrhizal habit. Their data, based on 17 pairs of taxa, indicate no differences in leaf N or phosphorus status after phylogenetic correction and imply that the mycorrhizal trait is correlated rather than causally related with these functional differences. Other claims about differences in N cycling between arbuscular mycorrhizal and ectomycorrhizal forests in the northern temperate zone may similarly indicate problems of establishing whether mycorrhizal status is a causally relevant or only a correlated trait. Thomas et al. (2010) showed a larger positive response to N deposition by arbuscular mycorrhizal than ectomycorrhizal trees, suggesting that the ability of the latter group to acquire organic N was traded off against the possibility of benefitting from increased inorganic N. Midgley and Phillips (2014) reported higher NO$_3^-$ leaching in arbuscular mycorrhizal forests than in ectomycorrhizal forests, but as
most of the data on arbuscular mycorrhizal forests pertain to maple (*Acer saccharum*) forests, the
generality of that pattern needs further study.

Averill et al. (2014) reported that competition between ectomycorrhizal fungi / plants and
decomposer microbiota results in N-limitation for the latter group, which retards litter
breakdown and hence results in increased C storage. They noted 70% more C storage per unit N
in ectomycorrhizal forests than in forests dominated by arbuscular mycorrhizal trees and
suggested that mycorrhizal status exerts a much larger control over soil C than climatic variables
at the global scale. However, this effect appears to be mainly driven by boreal trees (there is a
dominance in the database of ectomycorrhizal trees belonging to the Pinales and Fagales, both
orders that are characteristic for nutrient-poor soils) and the effect is only marginally significant
when the analysis is performed on temperate and tropical forests (Averill et al., 2014). Therefore,
plant traits that are inherently associated to mycorrhizal status should further be considered when
assessing the key drivers of the differential C:N stoichiometry and C storage.

Nitrogen immobilization in the mycorrhizal mycelium may also have a large impact on
the N cycle by reducing mineral N availability for plants. The general claim that mycorrhizal
symbioses are beneficial for the plant and that cases of a negative plant performance in the
mycorrhizal condition are explained by C costs of the symbiosis was refuted by Côrrea et al.
(2012), who concluded that smaller plant size was caused by lower N uptake. Lower N content
of the ectomycorrhizal plant could be due to mycorrhiza-driven progressive N limitation (Luo et
al., 2004). Alberton et al. (2007) showed this to be the case as plant N content was significantly
negatively correlated with hyphal length. Näsholm et al. (2013) showed that immobilization of N
in the ectomycorrhizal mycelium can aggravate plant N limitation. They modelled competition
between plant and fungus for N in a market model, and concluded that at N limitation the
symbiosis does not alleviate plant N limitation but in fact even reduces plant growth (Franklin et al., 2014; Kuyper and Kiers, 2014). Yet, despite this negative effect on plant performance, a non-mycorrhizal strategy is competitively inferior, and therefore trees are trapped as they cannot terminate the association. Because the biomass of the arbuscular mycelium is usually one or two orders of magnitude smaller than that of the ectomycorrhizal mycelium, the amount of N immobilized by the arbuscular mycorrhizal mycelium is sometimes hypothesized to be quantitatively unimportant from the plant’s perspective. However, recent studies (Hodge and Fitter, 2010; Grman and Robinson, 2013) indicate that N uptake and immobilization by arbuscular mycorrhizal fungi can also reduce plant performance.

Other pathways through which the mycorrhizal symbiosis may affect soil N cycling are modification of root exudation, root architecture, and fine root turnover (Churchland and Grayston, 2014). It is important to determine which of these differences are caused by the symbiosis and which by other root trait differences among species. For example, Comas et al. (2014) found that, after accounting for phylogenetic signals, ectomycorrhizal plants have thinner roots and greater branching intensity than arbuscular mycorrhizal plants. It is therefore a conclusion, it is still a matter of debate whether differences with respect to the mycorrhiza-associated nutrient economy (Phillips et al., 2013) are controlled by the mycorrhizal trait, or whether the mycorrhizal trait is instead correlated with causally relevant plant and climate traits. This needs to be resolved in the future.

4.4. N\textsubscript{2} fixation

An important share of bioavailable N enters the biosphere via biological fixation of atmospheric N\textsubscript{2} (BNF) (Vitousek et al., 2013). Biological N fixation can be natural (e.g. N\textsubscript{2}
fixing trees that are present in forest ecosystems) or anthropogenic (e.g. N₂ fixation by leguminous agricultural crops). Two types of BNF, both using the nitrogenase enzyme, are present in nature: symbiotic N₂ fixation (S-BNF) and free-living N₂ fixation (F-BNF). Symbiotic N₂ fixation is here defined via the infection of plant roots by bacteria - such as *Rhizobia*, *Bradyrhizobia* or actinomycetes - followed by the formation of nodules. All other forms of BNF are regarded as free-living N₂ fixation (including e.g. fixation by bacteria in soil and litter, but also N-fixation in lichens) (Reed et al., 2011). Here we highlight the importance of N₂ fixation for N budgets in pristine tropical forest, peatlands and cryptogamic soil crusts, as well as for sustainable production of biofuels.

Nitrogen demand in young successional tropical forest is high. The large fraction of leguminous plant species that forms symbiosis with N₂-fixing bacteria has recently been identified as a key element of functional diversity to overcome ecosystem-scale N deficiencies in tropical forest successions (Batterman et al., 2013a). Symbiotic fixation is thus considered to relieve N limitations and safeguard forest regrowth and CO₂-accrual as an ecosystem service. Nevertheless, S-BNF has also been postulated as the reason why mature tropical forest, having a lower N-demand than early succession stands, become relatively rich in N and as a consequence loses (sometimes large amounts of) bioavailable N (Hedin et al., 2009) via NO₃⁻ leaching (e.g. Brookshire et al., 2012) or gaseous N loss (e.g. Werner et al., 2007).

However, a plant-level physiological perspective counters this assumption, as numerous experiments have shown that symbiotic S-BNF by leguminous species is mostly facultative and down-regulated when located in an N-rich environment. Tropical leguminous species thus have the potential to fix atmospheric N₂, but it is likely that they only do so actively in young forest successions or disturbed ecosystems, and far less in mature forests. Secondly, only a part of the
The *Fabaceae* family has nodule-forming capacities (mainly belonging to the *Mimosoideae* and *Papilionoideae* subfamilies). This consideration decreases the omnipresence and abundance of potential N-fixers in tropical forests, making their role as a vital chain in the tropical N-cycle less credible. Therefore, Hedin et al. (2009) have suggested a possible mechanism for explaining this tropical N paradox via a ‘leaky nitrostat model’ (Fig. 5). This concept brings forward the importance of F-BNF, which is hypothesized to take place, even in N-rich ecosystems, in localized N-poor microsites, such as litter layers, topsoil, canopy leaves, lichens or bryophytes on stems, etc. Combined, these free-living N$_2$ fixers would bring high amounts of N in the system, resulting in high N availability. However, spatially explicit data are virtually absent and largely based on geographically biased, indirect measurements using the acetylene reduction assay rather than direct $^{15}$N$_2$ incubation measurements.

A recent spatial sampling method to assess total BNF indicated that tropical forest BNF is likely much lower than previously assumed (Sullivan et al., 2014). These authors reported mean rates of total BNF in primary tropical forests of 1.2 kg N ha$^{-1}$ yr$^{-1}$, while previous empirical or modeled data ranged between 11.7 and 31.9 kg N ha$^{-1}$ yr$^{-1}$. Secondary successional forests, as mentioned above, had higher total BNF than primary forest (6.2 – 14.4 kg N ha$^{-1}$ yr$^{-1}$). Sullivan et al. (2014) proposed a time-integrated total BNF rate of 5.7 kg N ha$^{-1}$ yr$^{-1}$ for primary forest in Costa Rica, of which 20-50% is attributed to S-BNF. It remains to be shown whether this BNF rate from primary tropical forest and proportions between S-BNF and F-BNF are valid for the pan-tropics. But if total BNF in tropical forests is indeed much lower than previously thought, this will fundamentally alter our assessment of tropical forest N cycles and the relative contribution of anthropogenic inputs (Sullivan et al., 2014). There is indeed emerging evidence that anthropogenic N deposition in tropical ecosystems is more substantial than assumed, as a
result of biomass burning, dust and biogenic deposition (Chen et al., 2010; European Commission-Joint Research Center, 2014; Cizungu et al., unpublished data). Hence, the relative contribution of human perturbation (e.g. wild fire, livestock fossil fuel combustion) to the tropical N cycle is likely much larger and warrants careful attention, e.g., by increasing N deposition measurement networks in tropical forests (Matson et al., 1999). Moreover, there is only limited understanding of the effects of proximate (N-, P- and Mo-availability) controls (Barron et al., 2009; Wurzburger et al., 2012; Batterman et al., 2013b), and the impact of global change factors (temperature, moisture, N-deposition) on F-BNF.

In boreal forests, symbiosis between cyanobacteria and feather mosses provides an important N-input (DeLuca et al., 2002; Gundale et al., 2012). In peatlands, which contain approximately 30% of global soil carbon, Sphagnum mosses living in close association with methanotrophic bacteria, which can stimulate BNF and constitutes an important mechanism for N accumulation in peatlands –(Larmola et al., 2014). These authors found N₂ fixation rates between 1 and 29 kg N ha⁻¹ yr⁻¹, up to 10 times larger than current atmospheric N deposition rates. This also shows that N₂ fixation contributes considerably to the N budget of peatlands. Cryptogamic covers that consist of cyanobacteria, algae, fungi, lichens and bryophytes are suggested to account for ca. half (49 Tg N) of the biological N₂ fixation on land (Elbert et al., 2012). From a sustainable agronomic management point of view, associative N₂ fixation could be promoted in certain crops. -For example, field experiments with sugar cane and Miscanthus with little N input showed that a substantial portion of new plant N was derived from N₂ fixation (Keymer and Kent, 2014).

While large uncertainties exist regarding the temporal and spatial variability, dominant determinants, and the magnitude and impact of BNF on terrestrial ecosystems functions and
services; even less is known regarding its future trajectories in view of global change.

4. 15N tracing modelling for understanding N cycling processes

The 15N enrichment techniques for investigating gross N transformation rates have recently been reviewed (Rütting et al., 2011b; Huygens et al., 2013). Therefore, this section will focus on how these techniques, combined with modelling, have helped advance our understanding of N cycling dynamics in soils.

The stable isotope 15N has been used as a tracer for the quantification of gross N transformation rates for 60 years. In their two seminal papers, Kirkham and Bartholomew (1954, 1955) developed the isotope pool dilution technique, enabling for the first time the quantification of gross transformation rates of N cycling processes. Quantification of gross rates has deepened our understanding of the terrestrial N cycle tremendously. For example, Davidson et al. (1992) showed that old-growth forests exhibit high gross mineralization rates, challenging the paradigm (based on net mineralization rate measurements) that these ecosystems have low mineralization activity. The isotope pool dilution technique is still widely used, even though it has some important limitations. The most crucial disadvantage is that only total production and consumption rates of a labelled N pool can be quantified, which may be the result of several simultaneously occurring N processes (Schimel, 1996). For example, gross nitrification as quantified by the isotope pool dilution technique can be comprised of two separate processes, autotrophic (NH₄⁺ oxidation) and heterotrophic (the oxidation of organic N to NO₃⁻) nitrification.

To overcome this limitation, 15N labelling can be done in conjunction with numerical 15N tracing models (Rütting et al., 2011b). These models describe the flow of N and 15N through the various
soil N pools (e.g. NH\textsubscript{4}\textsuperscript{+}, NO\textsubscript{3}\textsuperscript{-} and organic N), whereby transformations are represented by kinetic equations (e.g. zero- or first-order kinetics). The first \textsuperscript{15}N tracing model which could separate autotrophic from heterotrophic nitrification was presented by Myrold and Tiedje (1986). Subsequent studies using \textsuperscript{15}N tracing models have shown that heterotrophic nitrification can be a significant or even the dominant NO\textsubscript{3}\textsuperscript{-} production pathway in forest and grassland soils (Barraclough and Puri, 1995; Rütting et al., 2008; Taylor et al., 2013). In addition, \textsuperscript{15}N tracing models have been shown to be useful for investigating the importance of DNRA in various soils (Rütting et al., 2011a). Moreover, they can be used to distinguish DNRA from alternative pathways such as remineralization and plant efflux (Burger and Jackson, 2004). Recently an \textsuperscript{15}N amino-acid pool dilution approach has been developed (Wanek et al., 2010), which can be a useful tool for investigating whether depolymerization or N mineralization is the rate limiting step of the terrestrial N cycle (Schimel and Bennett, 2004), particularly if incorporated in numerical \textsuperscript{15}N tracing models.

In addition to quantification of gross N transformation rates, \textsuperscript{15}N enrichment has proven useful for partitioning nitrous oxide (N\textsubscript{2}O) emission sources. Using a two-source mixing model, Stevens et al. (1997) investigated the contribution of NO\textsubscript{3}\textsuperscript{-} reduction (i.e. denitrification) and NH\textsubscript{4}\textsuperscript{+} oxidation (i.e. autotrophic nitrification) to N\textsubscript{2}O emission. Subsequent work, however, suggested that organic N can be a third substrate for N\textsubscript{2}O production. Indeed, \textsuperscript{15}N studies using a triplet tracer approach and either analytical (Stange et al., 2009) or numerical (Stange et al., 2013; Müller et al., 2014) \textsuperscript{15}N tracing models showed a significant or even dominant contribution of oxidation of organic N (heterotrophic nitrification) to N\textsubscript{2}O production in soils. The numerical models have the additional advantage that gross N\textsubscript{2}O production rates can be quantified. Using oxygen isotopes (\textsuperscript{18}O) as an additional tracer allows the separation of NH\textsubscript{4}\textsuperscript{+} derived N\textsubscript{2}O
emission between \( \text{NH}_4^+ \) oxidation and nitrifier denitrification (Kool et al., 2011a)(See Section 2.2). A further step for understanding sources of \( \text{N}_2\text{O} \) emission from soil would be to incorporate \(^{18}\text{O}\) into numerical tracing models, i.e. development of a combined \(^{15}\text{N}-^{18}\text{O}\) tracer model. Overall, stable isotope labeling approaches (\(^{15}\text{N}\) and \(^{18}\text{O}\)) have greatly increased our understanding of the diverse N cycle processes contributing to \( \text{N}_2\text{O} \) production in soils. Moreover, these studies have confirmed the importance of \( \text{NO}_2^- \) dynamics for \( \text{N}_2\text{O} \) production (Stange et al., 2013; Müller et al., 2014) and for the soil N cycle in general (Rütting and Müller, 2008; Isobe et al., 2012), which deserves attention in future studies.

5. Conclusions

This is an exciting time to study the soil N cycle. Years of surprising findings on unanticipated pathways and mechanisms have expanded the horizons of researchers. These findings have stimulated efforts to develop and test new methods for quantifying these processes. This has resulted in a better understanding of the complexity of soil N cycling processes as well as powerful tools for future exploration.

Critical challenges remain. Many processes are still difficult to quantify and variability and heterogeneity hampers our ability to provide well constrained estimates relevant to water and air quality issues. We postulate that addressing the issues formulated above would constitute a comprehensive research agenda with respect to the N cycle for the next decade. Particularly, we urge the following blueprint for action:

(1.) to recognize Abandoning the long-disproven but persistent assumption that gaseous N production in soils is not the exclusively a result of the interplay between
nitrification and denitrification, and to focus on a better assessment of alternative gaseous N-producing pathways;

(2.) to dedicate continuous scientific efforts to the continuing development of improved techniques for the characterization, and quantification, and modelling of alternative N-transformation pathways, eventually in conjunction with state-of-the-art molecular techniques to determine the functional microbial communities involved; and

(3.) to consider ecological interactions and trophic cascades as indirect but essential drivers of soil N cycling, in particular in responses to global change.

Success will require interactions between soil science and other disciplines that address both smaller (e.g., molecular and microbial) and larger (ecosystems, landscapes and regions) scales.

We believe that such an agenda would help us meet future challenges on food and energy security, biodiversity conservation as well as climate stability.
Acknowledgments

The authors would like to thank the editors of SOIL for the invitation to write this review. J.W.V.G. and I.M.L. and J.W.V.G. were financially supported by an Netherlands Organization for Scientific Research (NWO; grant # 823.01.016.). P.G. was partially supported by U.S. National Science Foundation grant (grant # NSF DEB 0919131). D.H. and P.B. acknowledge the EU’s Seventh Framework Program for Research (grant # PIOF-GA-2011-301443) and the Fund for Scientific Research - Flanders (FWO). T.R. is financially supported by the Swedish strategic research area "Biodiversity and Ecosystem services in a Changing Climate - BECC". Finally, we are thankful to three anonymous reviewers for their extensive and constructive comments on an earlier version of our paper.

Author contributions

All authors contributed to selecting the topics addressed in this manuscript. P.B. wrote the sections on BNF and N₂O consumption; T.R. wrote the section on ¹⁵N models; D.H. and Th.W.K. co-wrote the section on mycorrhizal associations; D.H. wrote the section on rhizodeposition and plant traits; I.M.L. and J.W.V.G. co-wrote the section on soil fauna; J.W.V.G wrote the section on nitrifier denitrification; P.G. wrote the section on denitrification. J.W.V.G., D.H. and P.G. co-wrote the remaining sections. All authors commented on the final draft.

Figure captions

**Figure 1.** New insights and key challenges with respect to the soil N cycle, as identified in this manuscript. These include four three N cycling processes (Sections 2.1 - 2.43), a modelling challenge (Section 3) and three four pathways through which ecological interactions might affect proximal controls on N cycling processes (Sections 34.1 - 34.34), and a modelling challenge (Section 4).

**Figure 2.** The “leaky nitrostat” model adapted from Hedin et al. (2009), indicating the importance of symbiotic (S-BNF) and free-living (F-BNF) biological N₂ fixation along a forest successional gradient, from young (green) to mature (red) forest stands. At the initial stages of ecosystem succession, the N supply via S-BNF, F-BNF and N deposition supports high ecosystem N demands. In mature forest stands with a lower N demand, S-BNF is down-regulated, but N inputs via F-BNF and N deposition lead to ecosystem N losses via N leaching and gaseous N production.

**Figure 32.** Different pathways of N₂O production in soil. Classical nitrification by autotrophic bacteria or archaea (nitrifier nitrification); nitrifier denitrification by the same group of autotrophic bacteria; nitrification followed by denitrification (nitrification-coupled denitrification) and direct denitrification of applied nitrogen fertilizer (fertilizer denitrification). Reproduced from Kool et al. (2011a).
Figure 43. The N₂O production and consumption network showing five pathways for N₂O consumption. Dissimilatory N₂O reduction to N₂ via typical, denitrifier nosZ I (1), atypical, non-denitrifier nos Z II (2), dissimilatory NO₃⁻ reduction to NH₃ (DNRA) (3), direct assimilatory N₂O fixation via nitrogenase to NH₃ (4), and indirect assimilatory N₂O fixation (N₂O reduction to N₂ followed by N₂ fixation) (5); abiotic pathways that produce gaseous N (Feammox and chemo-denitrification are not shown).

Figure 54. The influence of soil fauna on soil N processes and loss pathways. Conventionally (a), these processes and loss pathways were often considered as the result of interactions between microbes and soil structure (a). More recently (b), it is recognized that many microbial and physical properties are influenced by faunal diversity through trophic relations and through changes in the soil structure by ecosystem engineers (b).

Figure 5. The “leaky nitrostat” model adapted from Hedin et al. (2009). This model indicates the importance of symbiotic (S-BNF) and free-living (F-BNF) biological N₂ fixation along a forest successional gradient, from young (green) to mature (red) forest stands. At the initial stages of ecosystem succession, the N supply via S-BNF, F-BNF and N deposition supports high ecosystem N demands. In mature forest stands with a lower N demand, S-BNF is down-regulated, but N inputs via F-BNF and N deposition lead to ecosystem N losses via N leaching and gaseous N production.
