May 21, 2016

Dear Dr Kristof van Oost

Thank you for finding the spelling mistakes and other small changes. We made all the changes suggested and these are depicted in purple and italics in the attached pdf. The other colors represents the changes made in the previous revised manuscript

Thanks so much for your time and effort

Best regards

Tammo Steenhuis and Mamaru Mogus
Sediment Concentration Rating Curves for a Monsoonal Climate: upper Blue Nile

Abstract

Information on sediment content in rivers is important for design of reservoirs and for environmental applications. Because of scarcity of continuous sediment data, methods have been developed to predict sediment loads based on few discontinuous measurements. Traditionally, loads are being predicted using rating curves that relate sediment load to discharge. The relationship assumes inherently a unique relationship between concentration and discharge and therefore although performing satisfactorily in predicting loads, it may be less suitable for predicting concentration. This is especially true in the Blue Nile basin of Ethiopia where concentrations decrease for a given discharge with the progression of the rainy monsoon phase. The objective of this paper is to improve the sediment concentration predictions throughout the monsoon period for the Ethiopian highlands with a modified rating type equation. To capture the observed sediment concentration pattern, we assume that the sediment concentration was at the transport limit.
early in the rainy season and then decrease linearly with effective rainfall towards source
limited concentration. The modified concentration rating curve was calibrated for the four
main rivers in the Lake Tana basin where sediment concentrations affect fish production
and tourism. Then the scalability of the rating type equation was checked in three hundred
hectare watersheds for which historic data was available. The results show, that for
predicting sediment concentrations, the (modified) concentration rating curve was more
accurate than the (standard) load rating curve as expected. In addition loads were predicted
more accurately for three of the four rivers. We expect that after more extensive testing over
a wider geographical area, the proposed concentration rating curve will offer improved
predictions of sediment concentrations in monsoonal climates.

Key Words: Africa, Horn of Africa, Ethiopia, Erosion, Tropics, Soil
1 Introduction

Only for a few rivers in the world and over a limited period, sediment concentrations have been measured at a daily or shorter frequency. In order to determine sediment loads in the absence of these measurements, models and rating curves have been used. Knowing the total sediment loads from rivers is essential for evaluating the siltation of reservoirs (Ali et al., 2014), assessment of soil erosion and nutrient loss (Walling, 1977). As a result knowledge of sediment concentration is important in most environmental applications because among others it hampers fish reproduction and reduce the esthetic value of surface waters (Vijverberg et al. 2012).

In the Blue Nile Basin, where the construction of the Grand Ethiopian Renaissance Dam is and planning of other hydroelectric dams are under way, determining sediment loads is becoming more urgent. At the same time concern for the environment has been increasing and it has been noted that the fish production in Lake Tana is decreasing due to increasing sediment concentrations (Vijverberg et al. 2012). Thus, the ability to predict accurately the sediment concentrations and loads to the lakes and man-made reservoirs has become important in the Ethiopian highlands where these are not available.

Modeling sediment loss is fraught with difficulties that unlike runoff is not bounded by the amount of rainfall. So there is no upper bound for sediment load in the absence of data. The models most commonly used for predicting soil loss are the USLE (Wischmeier and Smith, 1965) and its derivatives such as RUSLE (Renard et al., 1991) and MUSLE (Williams and Berndt, 1977) Hydrologic Engineering Center River Analysis System, (HEC-RAS, HEC 1995), Water Erosion Prediction Technology (WEPP, Nearing et al., 1989), Agricultural Non-Point Source Polution (AGNPS, Young et al.1989), Erosion Productivity Calculator (EPIC, Jones et al., 1991), Soil and Water Assessment Tool (SWAT, Arnold et al., 1998)
and Chemicals, Runoff and Erosion from Agricultural Environment Systems (CREAMS, Knisel, 1980). More sophisticated models used are the Neural Differential Evolution (NDE), Artificial Adaptive Neuro-fuzzy inference system(ANFIS), and Artificial Neural Network (ANN) Models (Masoumeh and Mehdi, 2012; Özgür, 2007). However, it is cumbersome to obtain the required data for these models especially in developing countries. The reason is that these models were originally developed for areas that have large amounts of data. For example, in the land use and land cover map, the leaf area index data that SWAT needs is not available. Similarly, the soil data in Ethiopia is very coarse and is missing basic information such as soil texture, hydraulic conductivity and other parameters that are difficult to measure in Ethiopia. Additional challenges using these models are: i) the models have been developed in regions with a semi-arid temperate climate where the runoff mechanisms are governed by Infiltration excess unlike the highland areas where saturation excess runoff is dominating (Steenhuis et al., 2009; Bayabil et al., 2010; Tilahun et al., 2013) and ii) almost all of the models need intensive data with many parameters that might be available centrally in developed countries but not in developing countries such as Ethiopia. Therefore, historically when concurrent concentration and discharge measurement were taken at irregular intervals; rating curves were often the preferred choice for predicting sediment loads (e.g., Walling, 1990) but also recently (e.g., Horowitz, 2010; Kokpinar et al., 2015; Choi and Lee, 2015; Kheirfam and Vafakhah, 2015). The abundance of papers on load rating curves in the refereed literature should be not surprising since purpose of the measurements was to determine the amount of sediment that potentially could be deposited in rivers and reservoirs. In the literature, a limited number of articles developed sediment rating curves. These few studies were carried out in Sweden (Fenn et al., 1985); Ontario Canada (Irvine and Drake, 1987), British Columbia in Canada (Sichingabula, 1998), South Australia (Sun et al, 2001) and for the Himalayan glacier in India (Arora et al., 2014).Thus, compared to the sediment load rating curves that are available throughout the world for many rivers, there are very few sediment concentration
rating curves and none for a monsoon climate.”

There is a connection between models and rating curves in sediment studies. Rating curves have been used to validate models. Previous simulations to predict sediment load in the Lake Tana basin such as Easton et al. (2010) and Setegn et al. (2009b), sediment load rating curves were used to generate the observed sediment load data and validate the models. Developing better rating curves will result in better predictions generated from observed flows.

There are at least 20 different ways to convert the measured concentration and discharge data to a rating curve (Phillips, et al., 1999: Horowitz, 2010). The most often used is a power function that relates sediment load (product of discharge and concentration) to discharge, (Miller, 1951; Muller and Foerstner, 1968; Phillips, et al., 1999; Masoumeh and Mehdi, 2012).

\[ M = a_l Q^b \]  

where \( M \) is the sediment load, \( Q \) is the discharge and \( a_l \) and \( b \) are rating curve parameters determined by regression analysis using observed data (Gao, 2008).

The concentration, \( C \), can be found by dividing the load (Eq. (1)) with the discharge \( Q \),

\[ C = \alpha_c Q^{l-1} \quad \alpha_c = a_l \]

The load rating curve Eq. (1) inherently assumes a unique relationship between discharge and concentration (i.e., \( \alpha_c \) is constant, Gao, 2008). However, when observed sediment concentrations are plotted against discharge, there is usually significant scatter around the curve (Asselman, 2000, Gao 2008 and Walling 1977) indicating that other factors in addition to discharge influence sediment concentrations. To compensate for variations, various modifications have been applied; these include dividing the sediment discharge
data into seasonal or hydrologic groupings, applying various correction factors, or using non-linear regression equations (Horowitz, 2010; Phillips, et al., 1999); In the Ethiopian highlands the scatter in the plot of discharge and sediment concentration is caused by the fact that the observed sediment concentrations in streams and rivers are decreasing for the same discharge with the progression of the rainy phase as shown for the Ethiopian highlands by Guzman et al. (2013) and Tilahun et al. (2013c). The same pattern has also been observed in Tibet in the upper reaches of watersheds by Henck et al. (2010).

Various reasons are given for the decrease in concentration with the progression of the rainy phase: Tilahun et al. (2013b) poses that with the progression of the rainy phase of the monsoon the value of $a_c$ is a function of the portion of newly plowed land takes the highest value in the beginning of the rainy season when in the unconsolidated soil rills form and the soil removed is transported by runoff. Nyssen et al. (2004), Vanmaercke et al. (2010), and Asselman (1999) showed that the sediment concentration depends on the sediment available for transport by runoff. Haile et al. (2006) and Awulachew et al. (2009) relate sediment concentration to the amount of plant cover protection which is increasing towards the end of the rainy period. However, Tebebu et al. (2010) noted that plant cover and sediment concentration were not statistically related. Zumr et al (2015) noted that sediment transport originated from saturation excess interflow from sloping agricultural fields and was not related to plant cover. Zegeye et al. (2010) and Tilahun et al. (2013c) attributed the decreased loading with the cessation of the rill formations. In addition, the base flow increases at the end of rainy phase and dilutes the sediment concentrations.

Since the traditional method of determining rating curves for sediment loads assumes that the sediment concentrations are a unique function of the discharge, this method cannot be used in environmental applications for predicting sediment concentrations when the sediment
concentration decreases throughout the season for a given amount of discharge. The objective of this paper is, therefore, to develop a realistic method in determining the decreasing sediment concentration with the progression of the monsoon using the limited data common in most of the tropics. The study is carried out in the Ethiopian highlands. Two groups of watershed sizes were selected to test how well the concentration rating curve performed. These consisted of four major rivers and their watersheds in the Lake Tana basin and three small well-monitored 100 ha watersheds in another part of the Blue Nile basin.

2 THEOREY: CONCENTRATION RATING CURVES

To include the observed decreasing sediment concentration with the progression of the rainy season in predicting sediment concentrations, Steenhuis et al. (2009) and Tilahun et al. (2013b,c) adapted the theory originally developed by Hairsine and Rose (1992). This relationship as depicted in Fig.1 is based on the assumption that the sediment load in the beginning of the rainy monsoon phase is at the transport limit when sediment is available from the plowed land and then linearly decreases with cumulative effective rainfall to a source limited concentration. Source limiting describes the condition when the rate of detachment from the soil determines the sediment concentration. Transport limiting, occurs when deposited and detached sediment are in equilibrium and the stream carries its maximum amount of sediment (Foster and Meyer, 1975). This is the case in the Ethiopian highlands when fields are plowed in the beginning of the rainy monsoon phase. Once the rill network is fully developed and stable, the sediment concentration will become source limited (Tilahun et al. 2013b). Finally as the surface runoff ceases and only base and interflow feeds the river, there will be small amount of sediments that the water picks up from the river bed or stirred up by animals or humans. Therefore, the sediment concentrations were calculated separately during the rainy monsoon phase and during the
dry phase. Since the start of the rainy phase varies from year to year and from one location to another, we will use the cumulative effective rainfall, $P_e$, to replace the “time” parameter. $P_e$ is determined by summing the daily effective rainfall which is equal to precipitation minus the potential evaporation for that day. The rainy phase starts when the cumulative effective rainfall, $P_e$, is greater than 40 mm (from observation) and setting each time when $P_e$ is negative to zero. As we will see later in most of the Lake Tana basin this occurs in the beginning of July, but it begins in mid-May in Gilgel Abay because the rainy phase starts earlier in a southern direction. For all of the watersheds the rainy phase ends the beginning of October.

Based on these observations we redefine the “$a_c$” in Eq. (2) for the rainy phase as:

$$a_c = \begin{cases} a_t + (a_s - a_t) \frac{P_e}{P_T} & \text{for } P_e < P_T \\ a_s & \text{for } P_e \geq P_T \end{cases}$$

(3)

where $a_s$ is sediment source limiting factor, $a_t$ is the sediment transport limiting factor, $P_e$ is the cumulative effective rainfall (mm) at a particular day, $P_T$ is the threshold cumulative rainfall up to which the $a_c$ parameter linearly decreases with cumulative rainfall, $P_e$, and after which the sediment concentration remains at the source limit. Thus, when $P_e$ is equal to or greater than $P_T$, the ratio becomes one, which indicates that the sediment concentration is equal the source limit. The “$a_c$” and “$a_s$” parameters depend on a number of factors such as slope length, particle size and disposability. In addition, “$a_s$” parameter varies with the cohesion of the soil (Yu et al., 1997). The threshold value was found in other simulations to be around 600 mm (Tilahun et al., 2013 a, b). The values of all three parameters are therefore difficult to predict a priori and need to be calibrated. As we will see hereafter they are in relatively narrow range indicating that they have some physical
meaning.

The value of the exponent b in Eq. (1) can be set to 1.4 when there is a linear relationship between velocity and sediment concentration and the depth of water is small compared to its width (Ciesiolka et al., 1995; Yu et al., 1997; Tilahun et al., 2013a b c). Using this value for b and combining Eq. (2) and (3), the modified concentration rating curve can be written for the rainy phase as:

\[ C = \left[ a_r + (a_s - a_r) \frac{P_e}{P_T} \right] Q^{0.4} \quad \text{for} \quad P_e < P_T \]  
\[ C = a_s Q^{0.4} \quad \text{for} \quad P_e \geq P_T \]  
(4a)

For the dry monsoon phase the concentration is

\[ C = a_s Q^{0.4} \]  
(4b)

The modified load rating curve can be obtained by multiplying Eq. (4) by Q. Then, for the rainy phase the load, M can be expressed as:

\[ M = \left[ a_r + (a_s - a_r) \frac{P_e}{P_T} \right] Q^{1.4} \quad \text{for} \quad P_e < P_T \]  
\[ M = a_s Q^{1.4} \quad \text{for} \quad P_e \geq P_T \]  
(5a)

And for the dry monsoon M can be expressed as:

\[ M = a_s Q^{1.4} \]  
(5b)
Materials and methods

The load rating curve (Eqs. (1) and (2)) and concentration rating curves (Eqs. (4) and (5)) are evaluated for the rivers in the four major watersheds in the Lake Tana basin: Gilgel Abay, Gumara, Megech and Ribb. These are named, hereafter, as the “Lake Tana Watersheds”. In addition, three small (approximately 100 ha) watersheds are selected for the assessment of scale effects in the concentration rating curve: Anjeni, Debre Mawi and Maybar. We will call these hereafter “100-ha watersheds”.

2.1 Description of study areas

The 15,000 km² Lake Tana basin is in the headwaters of the approximately 180,000 km² Blue Nile basin. The average annual discharge from Lake Tana is $3.8 \times 10^9$ m³ (3.8 BCM) which is approximately 7% of that of the Blue Nile at the Ethiopian Sudanese border (Awulachew et al., 2009). The elevation in the basin ranges from 1787 m to 4260 m. The major rivers that contribute 93% of the inflow to the lake are Gilgel Abay, Rib, Gumara and Megech. The gaging stations are located 95, 20, 26 and 40 km, respectively, to the lake inlet as shown in Fig. 2. The three micro watersheds are Debre Mawi, Anjeni and Maybar. The 91ha Debre Mawi and the 113ha Anjeni are located in the Blue Nile basin south of Bahir Dar at 35 km and 220 km respectively. The 112ha Maybar is just located on the boundary of the Blue Nile Basin near Dessie 300 km east of Bahir Dar. Average annual rainfall for all watersheds in this study varies between 1100 to over 1900 mm yr⁻¹ (Table 1).

3.2 Available Data

3.2.1 Discharge and sediment concentrations

Irregular measured discharge and sediment concentration data by Ministry of Water
Irrigation and Energy (MoWIE) for the major four rivers in Lake Tana basin were available from 1964 to 2008. The numbers of observations available for the Lake Tana watersheds used for this analysis period were 23, 53, 52 and 16 for the Gilgel Abay, Gumara, Ribb and Megech watersheds, respectively. The data of the 100-ha watersheds were collected for Anjeni and Maybar by ARARI (Amhara Region Agricultural Research Institute). The Debre Mawi data were collected partly by ARARI and us and is described in Tilahun et al. (2013 a, b).

The sediment concentrations in the Lake Tana watershed has been increasing since the initial measurement were made in 1964 (Ayana et al. 2014). We selected the following periods for analysis 1968-2008 for Gilgel Abay, Gumara and Rib. The Megech data was only available and the analysis was made for 1990–2007. The analysis for the Anjeni was made for 1996 and for Anjeni in 1994 when the watershed were stabilized from the soil and water conservation practices that were installed in the mid of 1980’s. For the Debre Mawi watershed the data in the years 2010 and 2011 were used before large scale conservation practices were installed in 2012.

**Climate data:** Rainfall and temperature data for the Lake Tana watersheds (Table 1) were available from 1994 to 2008 by the National Metrological Agency of Ethiopia (NMAE), Bahir Dar branch. The areal rainfall was calculated by using Thiessen-polygon method for the available rainfall stations for the Lake Tana watersheds as these watersheds have two or more rainfall stations. The method was chosen because it is simple and does not require additional information. Details are given in the supplementary materials (Supplementary Material, Table A1). The Anjeni and Maybar precipitation and temperature measured in the watershed were made available by ARARI. The precipitation data for Debre Mawi was collected by us on site. To fill the missing data the gage at Adet (8 km away) was used.
Temperature was obtained for the Adet station from the Adet Agricultural Research Center.

Potential evapotranspiration was estimated based on observed temperature data with the method developed by Enku and Melesse (2013).

Effective precipitation was calculated by subtracting the evaporation from rainfall each day. Cumulative effective precipitation was calculated during the rainy phase of the monsoon.

3.3 Methods

Rating curves were determined by either fitting the loads (i.e., the load rating curve) or the concentrations (concentration rating curve). Note that both the load and concentration rating curves can predict both the load and the concentration and thus the naming is based on the method of determining the rating curve.

The sediment load rating curve: The original MoWIE load rating curve was obtained for the Lake Tana watersheds by linearly regressing the logarithm of the sediment load versus the logarithm of the discharge for the period from 1964-2008. The slope of the line is $b$ in Eq. (1) and the intercept gives the value of $a_l$. These are listed in Table 1. In addition, we followed the same procedure to determine the rating curve for the 100-ha watersheds. Sediment concentrations were determined by dividing the load with the corresponding discharge.

The concentration rating curve: Rating curve was found by regressing the observed sediment concentrations and the discharge with Eq. (4). Four fitting parameters were required: Three for the rainy phase, i.e., the amount of rainfall $P_T$ after which the sediment is at the source limit and the source limiting factor $a_s$ and a transport limiting factor $a_t$. For
the dry phase the parameter, $a_b$, was required for the concentration in the base flow.

For the Lake Tana watersheds, precipitation and evaporation were only available for 1992-2000. In order to establish a $P_T$ value for the entire period for which discharge and sediment data were observed, average cumulative effective precipitation for the years from 1992-2000 as a function of the day was calculated for each watershed. For the 100-ha watersheds the average daily sediment concentrations and discharge and total rainfall data were available for the same years and the actual values of cumulative effective precipitation were used. Initial values for calibrating parameters ($a_t$ and $a_s$) were based on Tilahun (2013a, b) for Debre Mawi watershed. These initial values of ($a_b$, $a_s$ and $P_T$) together with $a_b$ were changed systematically till the best “closeness” or “goodness-of-fit” was achieved between measured and predicted sediment concentrations. The loads were obtained simply by multiplying the predicted concentrations by the observed discharge.

3.4. Statistical analysis

We first tested for outliers and those either less than half or more than twice the expected discharge or concentrations were removed from further analysis. In none of the cases not more than 5% the data points were discarded. The goodness of fit of the rating curves were determined with the correlation coefficient ($R^2$) and the Nash Sutcliff coefficient (NS). The goodness of fit for model performance was based on Moriasi et al. (2007), and rated as very good for $NS>0.75$; good, when $NS$ values was between 0.75 and 0.65; rated as satisfactory for values less than 0.65 but more than 0.5 and finally values less than 0.5 was considered poor.
4. RESULTS

4.1 Lake Tana watershed

4.1.1. Observed sediment concentration and load

The available sediment concentration data for the Lake Tana watersheds calculated from the sediment load of the Ministry of Water Irrigation and Electricity (MoWIE) are shown in Fig. 3. There were three periods when samples were taken for determining the rating curve. These were from 1964-1968, 1980-1996 and 2004-2008 (Fig. 3a and Supplementary Material, Tables B1 - B4). Gumara and the Ribb have the richest data set and the Gilgel Abay with only 23 data pairs is the poorest. Gumara and Ribb have also the greatest concentrations (Fig. 3). The concentration from the Megech is the smallest likely due to the Angereb man-made reservoir (which provides water supply for Gonder town) which was constructed in early 1980s.

When these concentration are plotted as a function of the day of the year independent of the year (Fig. 3b), the familiar pattern appears with the concentrations usually small in the base flow period form early October to the start of the rainy phase when concentrations increase. The elevated concentrations start around May 15 in the Gilgel Abay watershed which is earlier than the other watersheds because the rain starts earlier in this part of the watershed. The concentrations in the other watersheds start to increase in the late June (Table 2) and beginning of July The maximum concentration occurs in late June and early July (Fig. 3b) while the discharge is still relatively small (Fig. 3c) and decrease with progression of the rainy phase while discharge is elevated.
4.1.2 Evaluation of sediment concentration predictions

The relationship between the observed vs predicted sediment concentration for the Lake Tana watersheds are presented in Fig. 4 and the fitting statistics in Table 3. Both the concentration and sediment rating curves are used for obtaining the predicted sediment concentrations. Note that the concentration sediment rating curve refers to Eq. (4) and (5) and involves four fitting parameters. Best fit values are shown in Table 2. The concentrations with the load rating curve are obtained by fitting the loads first and then obtaining the concentrations by dividing the load by the discharge. Here we use the values obtained by MoWIE load rating curve in Table 1.

For the Lake Tana watersheds, the sediment concentrations are under predicted by the MoWIE load rating curve and indicated poor prediction performance (Table 3, Fig 4). The concentration rating curve fits the concentrations satisfactory with Nash Sutcliff values of 0.52 to 0.61 and $R^2$ values of 0.46 to 0.73 with slopes close to one (Table 3, Fig 4) The MoWIE load rating curves are poor in predicting concentrations.

4.1.3 Evaluation of sediment load predictions

Using the same rating curve parameters as in the concentration predictions above, the observed vs predicted sediment loads for the Lake Tana watersheds are shown in Fig. 5 and the goodness of fit in Table 4. The sediment loads (Fig. 6) are predicted satisfactorily to good with both the MoWIE load and concentration rating curves for Gilgel Abay, Ribb and Megech with $R^2$ values ranging from 0.61-0.84 (Fig. 5). The MoWIE load rating curve predicted the sediment load poorly for Gumara watershed. Generally, for the Lake Tana watersheds the concentration rating curves predict the loads more accurately than the MoWIE load rating curves with $R^2$ of 0.64-0.89 (Table 4) and slopes between 0.72 and
4.2 Results of the three 100-ha watersheds

After testing the sediment concentration rating curves for the Lake Tana watersheds, we investigated the applicability of the concentration rating curve for small watersheds. The three watersheds selected had good quality data. The concentration rating curve using Eq. (3) and (4) gave a reasonably good fit with the observed values (Fig. 6) with $R^2$ values ranging from 0.60 to 0.63 (Table 3) with values for the transport coefficients similar to the Lake Tana watersheds. The source limiting factor for Anjeni was the greatest and likely was caused by large active gully with unconsolidated soil that easily could be picked up by the flowing water.

5. Discussion

We will first discuss the loads and concentration predictions in the Lake Tana basin with the two types of rating curves followed by a comparison of the sediment load and concentration prediction with the concentration rating curve for the 100 ha and Lake Tana watersheds.

5.1 Predicting sediment concentrations (Lake Tana watersheds)

Similar to the predictions of the loads, the concentration rating curve fitted the observed concentrations better than those predicted by the MoWIE load rating curve. In addition to the reasons given for the poor fit (i.e. number of fitting parameters and log-log fit), the inherent assumption of a constant sediment concentration for the MoWIE rating curve was clearly problematic for fitting observed concentrations. In the Ethiopian highlands concentration are far from constant and follow usually a typical pattern where the concentrations are elevated during the beginning of the rainy season and decrease with the
progression of the rainy season (Fig 3b) while the discharge increases (Fig 3c). Again
similar to the loads, the Gilgel Abay fitted reasonably well because the concentrations were
reasonably the same during the rainy phase (Fig 3b, black dots).

5.2 Predicting sediment loads (Lake Tana watersheds)

For the Lake Tana watersheds, the concentration rating curve (Eq. (4)) fitted the observed
sediment load more accurately than the MoWIE load rating curve (Eq. (1)) as shown in Fig
5. The only exception was the sediment load predictions for the Gilgel Abay (Fig. 5a) that
was slightly better predicted by the MoWIE load curve than the concentration rating curves.
One could expect that the concentration rating curve would perform better because it has 4
fitting parameters compared to the MoWIE sediment rating curve with only two parameters.
In addition, there were few measurements taken early in the rain phase when sediment
concentrations could have been elevated (Fig 3).

However this does not explain the unexpected poor fit with slopes of much less than 1 for
the remaining three watersheds in the Lake Tana basin (indicating that the sediment loads
for the large storms are severely under predicted). This poor fit for the three watersheds
originates from using the log transformed values for fitting the sediment load and discharge.
To demonstrate that the MoWIE log rating curve fits the log transformed values well we re-
plotted Fig 5a in the auxiliary material (Supplementary Material, Fig C1) with a log scale.
The log transformed values give more weight to the small values of parameters than the
larger values. Thus, indeed using the log scale a good fit was obtained, while the same
points in the non-transformed values fit poorly (Fig 5a).

5.3 Concentration rating curve (100 ha and Lake Tana watersheds)

All fitting parameters for the concentration rating curve were remarkable independent of the
size of the watershed (Table 2). There was not a systemic difference in parameter values for the seven watersheds. The amount of effective rainfall \( (P_e) \) after which the concentration became independent of the rainfall (i.e., Eq. (4b)) varied between 561 mm/year for the Gilgel Abay and 599 mm/year for the Debre Mawi watershed. The difference among these values in all watersheds was not significant.

In further discussion of the sediment transport parameters we will exclude the Megech, since the gage station is located below the reservoir. Sediment is deposited in the reservoir and the parameters are not representative of the watershed that is subject to heavy gully formation. For the remaining six watersheds, the source factor \( a_s \) varied from 0.7 g/l (mm/day)^{-0.4} for Maybar to 1.8 g/l (mm/day)^{-0.4} for Anjeni. The smaller values are related to watersheds with a minimum of gully formation such as Maybar. The greater values are associated with watershed with active gully formation such as Anjeni, Gumara and Debre Mawi (Table 2, Tilahun et al., 2015; Dagnew et al., 2015).

There was a threefold difference in transport coefficients (but independent of watershed area as indicated in Table 2). It varies in the Lake Tana basin between 1.6 g/L^{-1} (mm/day)^{-0.4} for the Gilgel Abay and 5.9 g/L^{-1} (mm/day)^{-0.4} for the Gumara. The basic assumption in the concentration rating curve is that the sediment concentrations are determined by the transport capacity after land is plowed and rills are formed. Differences in the value for the transport coefficient can be related to the slope of the watershed since the transport coefficients are dependent on the stream power and the stream power is a function of slope (Gao 2008). The Gilgel Abay has 22% of land in the lowest slope category (0-2%) which is three times that in Ribb and Gumara. Moreover, the Gilgel Abay has only 1% in slope of greater than 30% while the other watershed have 9% or more in this category. Similarly Anjeni, in which most land is terraced, has gentle slopes and a small transport coefficient
compared to the Maybar and Debre Mawi watersheds that do not have terraces and have agricultural land with greater slopes. In both Gilgel Abay (Fig. 3b) and the Anjeni (not shown) watersheds, the concentrations in the beginning of the rainy phase are less pronounced than the other four watersheds. Thus, the low value of the transport coefficient is most likely related to the slope of the cultivated land in the watershed.

Finally the “ab” values that determine the concentration during base flows are related to the stream channel erosion that in the case of the Gumara has the greatest value. This can be related to several factors mainly increasing population and activities for natural resource competition. This includes pumping water for irrigating cash crops during the dry monsoon phase from the river. In addition, sand is being mined from the river bed.

6. Conclusions

In the Ethiopian highlands sediment concentrations in the rivers decrease with progression of the rainy phase of the monsoon. Using this observation while developing the sediment rating curve significantly improves for predicting the sediment concentration and load. The method developed by the Ministry of Water Irrigation and Energy and used for predicting daily loads throughout Ethiopia will likely remain the method of choice for most rivers especially for larger basins where concentrations remain relatively constant. Although more research has to be done, there is an indication that the coefficients in the newly developed concentration rating curve can be related to landscape characteristics. Therefore, these parameters might have physical meaning which would help to generate the parameters from the physical watershed characteristics for the ungaged catchments for predicting concentrations and load in the upper Blue Nile Basin.
Acknowledgments

Funding for this program is provided by the US Agency for International Development (USAID) through PEER Science program and Higher Education for Development (HED), International Science Foundation (ISF). The runoff and sediment data were made available by Ministry of Water and Energy. We would like to thank MoWIE for making the rating curve data available to us.
