Abstract

There is need to understand soil system response to warming in order to model soil process response to predicted climate warming. Current methods for soil warming include expensive and difficult to implement active and passive techniques. Here we test a simple, inexpensive in situ passive soil heating approach, based on easy to construct infrared mirrors that do not require automation or enclosures. The infrared mirrors consisted of 61 x 61 cm glass panels coated with infrared reflecting film. The mirrors as constructed are effective for soil heating in environments typified by open canopy. Mirror tests were performed on three soils of varying texture, organic matter content, and heat capacity in a warm semiarid environment. Results indicated that the infrared mirrors yielded significant heating and drying of soil surface and shallow subsurface relative to un-warmed control treatments, and that warming and drying effects was soil specific with greater potential warming on soils with lower volumetric heat capacity. Partial shading from the mirror frame did produce periods of relative cooling at specific times of the day, but overall the mirrors yielded a net soil warming. The results demonstrate proof-of-concept that the infrared mirrors may be used to passively heat the near soil surface, providing an inexpensive, low-maintenance alternative to other passive and active soil heating technologies.
1 Introduction

Climate change and warming present significant challenges to understanding future ecosystem response, function, and management. The most recent projections suggest up to a 5 °C warming by the end of this century, with mean winter and summer warming of 3.8 °C and 3.3 °C, respectively (IPCC, 2014). Given these projections, there is pressing need to understand the response of soil systems to warming, particularly changes in soil-water and -energy budgets, and soil biogeochemical processes such as carbon and nitrogen cycling. Experimental methods for soil and ecosystem warming include temperature controlled environments in laboratory and greenhouse settings, moving intact soil cores across natural environmental gradients, and heating of soils in situ using various active and passive approaches (Aronson and McNulty, 2009). All of these methods have their short-comings, e.g., extrapolating results from controlled environments to the field, requirement of aboveground enclosures for passive in situ soil heating, and equipment and operational costs associated with active in situ heating. Currently, an inexpensive and effective alternative for in situ soil heating that does not require an aboveground enclosure is lacking.

Soil and ecosystem heating methods vary widely and have been reviewed in detail in Rustad et al. (2001), Shaver et al. (2000) and Aronson and McNulty (2009). Here we highlight several of the main passive and active methods used in previous field studies as context for the approach tested in this work. Many studies apply active heating methods such as infrared heaters (Harte et al., 1995), cables buried in the soil (Peterjohn et al., 1993), with more recent approaches including a combination of steam injection and passive aboveground enclosures (Hanson et al., 2011). Active methods effectively heat above- and below-ground systems with significant changes observed as a result of heating in plant species composition, soil respiration, and soil-water content (Shaver et al., 2000). However, these methods are expensive in terms of equipment set up, operational costs and energy consumption, and require proximity and access to electricity. Passive methods generally include open top chambers and greenhouses placed over mesocosm plots in the field (Kennedy, 1995); however these approaches exclude and minimize the turbulent transfer of air, energy and water vapor, and the movement of mass into and out of the experimental enclosure. Another passive heating approach consists of nighttime trapping of longwave radiation from the soil with an IR reflective sheet above the soil surface that effectively warms the soil overnight (Beier et al., 2004). However, this requires
an automated system to lower the IR sheet over the soil surface in the evening and to raise the
IR sheet in the morning.

Here we present a simple, inexpensive in situ passive soil heating approach based on
easy to construct IR mirrors that do not require automation or enclosures. The objective of this
work was to empirically test the efficacy of these mirrors for heating the soil surface and
shallow subsoil under field climate conditions.

2 Materials and Methods

2.1 Infrared mirror design

The infrared mirrors consisted of 61 x 61 cm glass panels mounted in a 5 X 5 cm
redwood board frame (Fig 1). The size of the mirrors were limited to relatively small glass
panels for stability and ease of transfer for this proof-of-concept study, but future applications
could implement larger glass panels for more permanent installations. The glass panels were
mounted in the frame at a height of 15 cm above the ground surface; with the 5 X 5 redwood
frame this leaves an air gap of 10 cm between the bottom of the frame and the ground to allow
of air flow and mixing around the base of the panel. The panel glass consisted of common
double strength window glass 3 mm thick. The side of the glass away from the plot was covered
with Gila Titanium heat control window film (Eastman Chemical Performance Films Division,
Gila Film Products, St. Louis, MO, USA). The frames in the field were mounted facing true
south, tilted back 10° from vertical (top of frame tilts away from the plot), and secured with
metal t-posts. The glass absorbs ultraviolet light and the film reflects up to 72% of incoming
long wave radiation towards the soil surface according to manufacturer specifications.

2.2 Field experiments

The mirrors were tested using a series of field experiments designed to quantify the
effect of mirrors on surface and shallow subsurface soil temperature. The experiments
consisted of a set of initial field trials followed by a larger scale test with multiple replicated
plots on different soil types. The size of the mirrors is best suited to heating soil in low-stature
ecosystems, making them ideal for grassland, short scrub, tundra, and agriculture studies.
2.2.1 Initial field trials

Initial field trials were carried out at the Karsten Turfgrass Research Facility located at the University of Arizona Campus Agricultural Center (CAC) in Tucson, AZ at 32° 16’ 51.77” N, 110° 56’ 3.14” W, at an elevation of 715 m a.s.l. The average climate at this location includes a mean annual air temperature of 22.4 °C, mean annual potential evapotranspiration of 1,945 mm yr\(^{-1}\), and mean annual precipitation of 275 mm yr\(^{-1}\) characterized by a bimodal precipitation regime where ~50% of precipitation derives from cool, winter rains and ~50% arrives during the summer as part of the North American Monsoon, with warm dry periods in the spring and fall. Meteorological data for 2013, the year of observation, fell within climatological norms with a mean temperature of 20.4 °C, potential evapotranspiration of 1,933 mm, and annual precipitation of 190 mm. Meteorological data were measured hourly at the CAC using a weather station managed as part of the Arizona Meteorological Network following standard techniques. The station is <0.5 km from the study site and data are freely available online (AZMET, 2013, http://ag.arizona.edu/azmet/). The soil at the study area was classified as a coarse-loamy over skeletal, mixed, superactive, calcareous, hyperthermic Typic Torrifluvent (http://websoilsurvey.sc.egov.usda.gov/App/WebSoilSurvey.aspx), with a fine sandy loam surface soil that contains 4-7% clay based on hand texturing, and < 0.5% organic matter. The parent material was granitic alluvium from the Rillito River and associated local drainages.

The mirrors were placed in an area free of vegetation and groundcover to facilitate direct heating of the soil surface. The initial mirror array consisted of one replicate three mirrors facing south; the central mirror facing due south, with a mirror on each side at an angle of 130° relative to the south facing mirror (Fig. 1). The side mirrors resulted in significant shading of the plot in morning and early evening. As such, following an initial monitoring period of three months starting in March 2013, the side mirrors were removed in sequence, leaving only the central south facing mirror. Data were collected for an additional three months starting in June 2013 following side mirror removal.

Surface and shallow subsurface soil temperature were recorded using 12-bit Temperature Smart Sensor (S-TMB-M006) attached to an HOBO Micro Station Data Logger (H21-002; Onset Computer Corporation, Bourne, MA, USA) set to record on a 15-minute interval. The surface thermocouple was placed directly on the soil surface and the shallow subsurface probe was placed 5 cm below the soil surface. Control thermocouples were placed
adjacent to the mirror plot and linked to the same data-logger; roughly 1 m separated the control and test plots.

### 2.2.2 Replicated plots

The replicated field experiment was also located at the CAC in a field adjacent to the test plot location. The replicated field experiment was part of a larger project examining the role of soil amendments on two different soils on native vegetation establishment in stockpiled topsoil from an open pit mine. The two soils used in this experiment were collected at 31° 50’ 34.30” N, 110° 45’ 05.96” W, 1615 m a.s.l., and 31° 49’ 20.48” N, 110° 44’ 03.62” W, 1500 m. a.s.l., and mapped as the Chiricahua and Hathaway soil series, respectively (USDA Web Soil Survey, accessed 2015, http://websoilsurvey.sc.egov.usda.gov/). The Chiricahua soil (CHIR) was derived from a mix of metamorphic rocks and classified as an Ustic Haplargid; the Hathaway soil (HATH) was derived from mixed sedimentary rocks, largely sandstone, and classified as an Aridic Calciustoll (USDA Official Soil Series Descriptions, accessed 2015, https://soilseries.sc.egov.usda.gov/osdname.asp). The soils were excavated mechanically to a depth 1.75 m below the soil surface and delivered to the CAC. Soils were sieved in the field to remove coarse fragments > 15 cm in diameter before placement in experimental mesocosms.

The replicated field plots consisted of mesocosms constructed in place at the CAC. The mesocosms were located in an open field and subject to ambient climatic conditions. The mesocosms consisted of square excavations that were 0.91 m on a side and excavated to a depth of 30 cm below the soil surface. The square excavation was lined in porous geotextile fabric that allows for water flow but prevents soil in the mesocom from mixing with the exant soil. The mesocosms were backfilled with the Chiricahua and Hathaway soil material up to the level of the soil surface (Fig. 1).

The replicated field plot experimental design consisted of a randomized complete block design, with each mesocosm randomly assigned to soil type (either Chiracahua or Hathaway), control (no mirror), and mirror (IR mirrors), with four replicates of each treatment. Plots with IR mirrors were equipped with two adjacent IR mirrors oriented due south, tilted back 10° from vertical, and secured with metal t-posts (Fig 1). Two mirrors were used to ensure greater coverage of the mesocosm with re-radiated IR energy. It was assumed that the shading effects from the mirror frame was minimal.
The CHIR and HATH soils varied in texture and coarse fraction content, color, and organic matter. Particle size analysis was quantified by laser particle size analysis following removal of organic matter. Weight percent coarse fragments was quantified as the fraction not passing a 2 mm sieve. Dry and moist soil color were measured using a Spectron CE-590 spectroradiometer (Spectron Instruments, Denver, CO) and converted to Munsell notation, and organic matter quantified as loss on ignition (LOI) following 2 hr combustion at 500 °C. Soil properties were measured at University of Arizona Center for Environmental Physics and Mineralogy. Soil color was used to estimate dry and moist soil albedo (0.3-2.8 µm) (α) following Post et al. (2000) as: 
\[ \alpha = 0.069v - 0.114, \]
where \( v \) is the Munsell soil value. The volumetric heat capacity of the different soils in each mesocosm, \( C_T \), was calculated as (Jury et al., 1991; Kluitenberg, 2002):

\[ C_T = (C_OX_O + C_SX_S + C_RX_R)(1 - \phi_T), \]  
(1)

where \( C_O, C_S, \) and \( C_R \) are the volumetric heat capacities of organic matter, soil, and rock with values of 2.5, 1.9, and 2.4 kJ kg\(^{-1}\) K\(^{-1}\), respectively (Eppelbaum et al., 2014; Kluitenberg, 2002), \( X_O, X_S, \) and \( X_R \) are the volume fractions organic matter, soil, and rock in the mesocosm, and \( \phi_T \) is the total porosity of the mesocosm calculated assuming the volume rock fraction has zero porosity and soil bulk density calculated following Rawls (1983). The values for \( C_T \) were calculated assuming a zero water content to provide a dry reference volumetric heat capacity for each soil type. These data provide a direct measure of the amount of heat required to warm the soil system, such that for soils of varying heat capacity receiving the same amount of heat energy, the soil with a greater heat capacity will record a decreased temperature increase relative to the soil with a lower heat capacity.

Repeated measures of surface soil temperature were recorded with a handheld IR thermometer (Cen-Tech model 60725, Cen-Tech, Camarillo, CA, USA) from a height of approximately 1 meter above the soil surface on six dates between August 20 and September 24, 2013. The IR thermometer was used in the replicated field plots due to the fact that the relatively high number of replicates limited instalation of thermocouples and dataloggers for all replicate plots. Repeated measures of soil moisture measured were recorded using FieldScout TDR 100 Soil Moisture Meter (Spectrum Technologies Inc. Plainfield, IL, USA) with 10 cm probes on sixteen dates between August 22 and October 15, 2013.
### 2.3 Data manipulation and statistical analyses

The relative soil heating by the IR mirrors in the initial field trials was calculated as:

\[
\Delta T = T_{IR} - T_C, \tag{2}
\]

where $\Delta T$ is the relative increase or decrease in soil temperature, $T_{IR}$ is temperature in the IR mirror plot, and $T_C$ is temperature in the control plot, both in degrees Celsius. Statistical analyses for the initial field trial included simple summary statistics for $\Delta T$ values and correlation of $\Delta T$ to meteorological variables collected at the nearby AZMET station.

Statistical analyses for the replicated plot experiment included summary of soil temperature and moisture by soil type, with means comparison of surface $\Delta T$ and the difference in soil moisture between mirror and control, $\Delta \Theta_v$, treatments by soil type. Prior to statistical analysis, temperature and moisture data for the four replicate plots of mirror and control treatments for each soil type were averaged by date. The relative difference in surface temperature, $\Delta T$, and soil moisture, $\Delta \Theta_v$, between mirror and control plots was calculated as the difference between the means for each treatment for each soil type. Significant differences in $\Delta T$ and $\Delta \Theta_v$ by soil type were determined on the means of all observation dates using an unequal variance t-test. Additionally, $\Delta T$ and $\Delta \Theta_v$ were correlated with local meteorological variables from the AZMET station. All statistical analyses were performed using JMP Pro 11.0.0 (SAS Institute, Cary, NC).

### 3 Results and Discussion

#### 3.1 Initial field trials

The initial field trial with the three mirror array yielded substantial warming of the shallow subsurface soil (5 cm depth), with maximum midday warming near 17 °C relative to the unheated control plot (Fig. 2). Heating was greatest between the hours of 1100 and 1300 hrs when the sun was at its highest point in the sky with a mean $\Delta T$ of 1.1 °C. However, as the year progressed from early spring to summer and the sun moved further to the north, substantial cooling of the mirror plot was observed in the morning and evening hours, with a concurrent reduction in midday heating (Fig 2). In particular, the afternoon temperature differential indicated the mirror plots were up to 5 °C cooler at a 5 cm depth than the control plot. The
morning and afternoon cooling was due to shading from the side mirrors oriented at 130°
relative to the central south facing mirror.

We conducted several short-term experiments with the three mirror array to try and
address the morning and afternoon shading. The first experiment simply included changing the
angle of the side mirrors from 130° to 160° relative to the central south facing mirror, between
days 141 and 154. Opening the mirrors did reduce the amount of shading and increase the
hours of warming, but yielded a mean ΔT value near -0.2 °C, with brief periods of 4-5 °C
cooling in the afternoon hours (Table 1). The second experiment ran from day 154 to 164 and
included removing the west panel to try and eliminate the afternoon cooling trend. This
experiment did yield a reduction in both morning and afternoon cooling and returned the mean
ΔT to an overall warming trend of 0.5 °C.

The final field trial experiment consisted of removing both side mirrors, leaving just the
one south facing mirror. In this instance, soil temperature was measured both directly at the
soil surface and at a 5 cm depth. The data indicated mean ΔT values of 0.5 and 0.3 °C at the
surface (Fig. 3a) and 5 cm depth (Fig. 3b; Table 1). Both surface and 5 cm depth temperatures
exhibited the greatest heating at midday, with maximum ΔT values near 10 °C and 5 °C,
respectively. Periods of cooling were still evident in the morning and afternoon hours. Detailed
observation of diurnal ΔT trends indicate cooling between the hours of 0800 and 1000 that was
then overcome by heating during the midday hours. Of the ~2,300 hourly average ΔT values,
64% and 67% of observations were ≥ 0 °C for surface and subsurface soils, respectively, such
that the majority of observations indicated warming (Table 1). The majority of hours that
indicated cooling exhibited ΔT values between -1 °C and -2 °C, with less than 2% and 0.7% of
surface and subsurface measurements, respectively, recording cooling greater than -2 °C.

Comparing the one-mirror ΔT values to meteorological variables indicated that the
relative cooling in mirror plots was greatest during periods of high atmospheric moisture and
following precipitation events when surface soils were moist (Fig 4a). This was evidenced by
significant negative trends in ΔT with both mean daily dewpoint (Fig 4b) and daily minimum
relative humidity (Fig 4c). Both of these values provide a measure of atmospheric moisture
content, with the mean daily dewpoint a daily average and minimum relative humidity
providing a measure of atmospheric humidity at the hottest point in the day. These data clearly
indicate that the warming effect of the mirror was minimized or negated with a wet atmosphere.
This trend was particularly evident in the 5 cm depth ΔT values following rainfall events.
Detailed diurnal analysis of 5 cm ΔT values indicated that during wet periods following rainfall events the midday heating from the mirror was not enough to overcome any cooling associated with morning and afternoon shading. These data were consistent with both atmospheric and soil moisture limiting temperature increases in the shallow subsurface. Furthermore, the increased energy transfer to the soil in the mirror plot may also have increased evaporation rates that would buffer any warming as energy was consumed via vaporization (e.g., Wåhlin et al., 2010). However, soil moisture was not monitored during the initial field trials. These data highlight that the greatest warming impact of mirrors was during periods with dry soil and atmospheric conditions, and also suggest the potential for changes in surface soil water balance that would lead to more evaporation and soil drying in the mirror treatments.

3.2 Replicated plot experiments

The replicated field plot experiments indicated significant heating of the soil surface with an average ΔT of +5.5 °C (Fig. 5; Table 2). These measurements were single time points collected during the midday time period; as such they represent near maximum temperature differentials based on the continuous data patterns collected in the initial field trial. The relative warming also varied significantly by soil type, with HATH exhibiting ΔT of +6.8 °C and CHIR exhibiting ΔT values of +4.1 °C (Table 2). The CHIR plots contained a larger fraction of rock fragments, lower estimated total plot porosity, and higher heat capacity that would also limit temperature change per unit of additional IR radiation (Jury et al., 1991) (Table 2).

The replicated field plot ΔT values exhibited a general negative trend with increasing minimum daily relative humidity across all sampled dates (r = -0.32) (Fig. 5), confirming the field test trials where warming from the mirrors was attenuated by atmospheric and soil moisture. The date that deviated most substantially from this overall trend was the last date collected on day 267, noted in Fig. 5. This measurement date was preceded by the largest series of rainfall events during the observation period that corresponded to increased soil moisture content in both the CHIR and HATH soils. The lack of differential heating at this time period despite relatively low minimum relative humidity values was thus likely controlled by soil moisture content. Excluding this day, the correlation between ΔT and minimum daily relative humidity increased and became significant (r = -0.66; P<0.05).

Soil moisture data indicated a relative drying trend in the mirror plots, with significantly greater drying in the HATH relative to the CHIR soils (Fig. 6; Table 2). The CHIR soils
exhibited high rock fragment content, coarse textured fine-earth fraction, and only 13% total mesocosm porosity leading to both a limited water holding capacity and faster drainage relative to the HATH mesocosms (Table 2). This was confirmed by soil moisture data from the control mesocosms that indicated CHIR soils averaged 13.6% volumetric water content relative to 22.7% in the HATH soils and that for each day of observation, the CHIR soils were drier than the HATH soils by 5 to 15% volumetric water content. The CHIR soils also exhibited a greater volumetric heat capacity in the solid phase that would limit the transfer of heat energy to soil water and vaporization. In contrast, the HATH soils exhibited fewer coarse fragments, greater clay and silt content, and greater porosity, indicating greater water holding capacity in addition to a lower volumetric soil heat capacity of the solid fraction. These factors favor warming of the soil and greater transfer of absorbed energy to soil water, favoring soil water vaporization. The drying results are similar to results of Harte et al. (1995) and Verburg et al. (1999) that found significant drying with IR lamps and soil heating cables, respectively.

### 3.3 Mirror success, limitations, and future directions

The results from this proof of concept study indicated that the IR mirrors do effectively heat the near soil surface, but also highlights a number of limitations and future directions for research to improve mirror implementation in the field.

**Mirror successes include:**

- The mirrors are inexpensive to construct and can be easily installed in any number of field settings;
- The infrared mirrors yielded significant heating and drying of soil surface and shallow subsurface relative to un-warmed control treatments, with an average soil warming of 4 to 7 °C, and average decrease in soil moisture by 1 to 6%, depending on soil heat capacity.

**Mirror limitations include:**

- Periods of shading from the wooden frame;
- Relatively uncontrolled heating of the soil surface that is sun angle dependent;
- Poor constraint on how the mirrors will work in areas with relatively dense understory vegetation;
- Unknown potential for scaling to cover larger areas and relatively poor constraint on the actual area heated by the mirror.
Future research directions include:

- Redesign of the mirror frame to minimize shading. Most shading appeared to derive from the framing at the bottom of the mirror; the shading can be minimized by redesign of the mirror frame, such as only framing on the sides of the mirror;
- Empirical measures of the heated area with an array of thermocouples and possibly an IR camera to measure the exact area heated by the mirror and any temperature gradients that exist at the warming boundaries;
- Installation of mirrors in areas with more complete vegetative cover, including both grasses and shrubs/trees, to determine effectiveness for soil warming in vegetated settings;
- Numerical modeling that incorporates various mirror size, angle, sun angle, latitude, and cloud cover to optimize mirrors for specific environmental settings.

4 Conclusions

The results presented here demonstrate proof-of-concept that the infrared mirrors tested here may be used to passively heat the near soil surface, providing an inexpensive, low-maintenance alternative to other passive and active soil heating technologies. The mirrors as constructed were effective for soil heating in environments typified by open canopy and low canopy vegetation, similar to those present in agriculture systems, desert grassland and scrub ecosystems. Heating from the infrared mirrors significantly impacted both soil warming and drying, similar to trends expected with a warming climate. Key conclusions include:

- The infrared mirrors yielded significant heating and drying of soil surface and shallow subsurface relative to un-warmed control treatments;
- Atmospheric and soil moisture attenuated IR mirror-induced soil warming;
- The warming and drying effects of the infrared mirrors was soil specific, with greater potential impact on soils with lower volumetric heat capacity.

It is important to note that the initial field trials indicated soil warming from the infrared mirrors was more pronounced in winter months when the sun was further to the south, and that periods of shading related to the frame and mirror orientation were apparent in morning and evening hours. The efficacy of soil heating with the infrared mirrors could be improved with detailed numerical modeling of coupled soil-atmosphere energy and water balances that take into account latitude, seasonal changes in sun position, and soil moisture and heat capacity, e.g., using a model such as HYDRUS 1D. Such modeling would facilitate optimization of mirror angle, size, and orientation to reach the desired experimental soil warming and drying response.
Additional modeling coupled with field instation of infrared mirrors in different environments have the potential to make this type of infrared mirror a powerful tool for experimental warming of open canopy and low vegetation canopy systems.
